More realistically, when N and Ri are large but finite, and when f is finite, $\partial/\partial z$ reappears in the problem and brings back vertical coupling. The flow remains layerwise-two-dimensional in the sense that notional 'PV particles' move along each isentropic surface $\mathcal{S}$ – see *Impermeability Theorem* below – but the surfaces $\mathcal{S}$ themselves are no longer quite horizontal, nor quite rigid. Aside from the vertical advection that moves and tilts the surfaces $\mathcal{S}$, all the vertical coupling comes from the PV

inversion operator. The two-dimensional inverse Laplacian in [14] is replaced by an inverse elliptic operator that qualitatively resembles a three-dimensional inverse Laplacian when a stretched vertical coordinate Nz/f is used; thus the vertical coupling for flows of horizontal scale L is effective over a height scale of the order of the corresponding Rossby deformation height fL/N .

For finite N and Ri there are tradeoffs between accuracy and simplicity. The mathematically simplest though least accurate three-dimensional PV inversion operator is that arising in the standard Charney–Obukhov quasigeostrophic theory, an asymptotic theory whose approximations are valid away from the equator, for large Ri and small Rossby number $Ro \sim Ri^{-1/2}$, where Ro can be defined as f_0^{-1} times a typical relative-vorticity value with f_0 a constant representative value of the Coriolis parameter f . The price paid for the mathematical simplicity includes resorting to a strange double subterfuge in which, first, we retain only the purely horizontal velocity field $\mathbf{u} = \hat{\mathbf{z}} \times \nabla_H \psi$ even though vertical motion is now significant and, second, abandon P , the exact, Rossby–Ertel PV, which is advected by vertical as well as by horizontal velocities, in favor of a so-called *quasigeostrophic potential vorticity*, q , advected by the horizontal velocity only. For background $\rho = \rho_0(z)$ and $N = N_0(z)$ we may define

$$q = f + \nabla_H^2 \psi + \frac{1}{\rho_0} \frac{\partial}{\partial z} \left(\frac{\rho_0 f_0^2}{N_0^2} \frac{\partial \psi}{\partial z} \right) \quad [15]$$

noting the agreement with [13] in the limit $N_0 \rightarrow \infty$, apart from the factor σ^{-1} . Omission of that factor is part of the subterfuge, making vertical advection implicit. The generalized ballerina effect is now hidden inside the last term of [15]. The isobaric anomalies in T and θ , measuring small displacements and tilting of the isentropic surfaces $\mathcal{S}$, are proportional to $\partial \psi / \partial z$. For instance if $\theta_0(z)$ denotes the background potential temperature, so that $N_0^2(z) = g d \ln \theta_0 / dz$, then we have $\theta - \theta_0(z) = g^{-1} \theta_0 f_0 \partial \psi / \partial z$ within the approximations of the theory.

The most efficient way of describing the relation between q and P is to say that $\nabla_H q$, the local horizontal or isobaric (constant- z) gradient of q , is proportional to $(\nabla_H P)_\theta$, i.e., proportional to the corresponding isentropic gradient of P . Isobaric eddy fluxes of q are correspondingly related to isentropic eddy fluxes of P .

From [15] we see that the electrostatic analogy holds, qualitatively, in three dimensions, with stretched vertical coordinate $N_0 z / f_0$. The electric-charge distribution is $q - f$. This can include Bretherton delta functions. If we impose $\partial \psi / \partial z = 0$ at the lower boundary, for instance, when inverting [15] to get ψ from q , then a delta-function contribution to the last term of [15] can accommodate finite $\partial \psi / \partial z$ just above the boundary, hence a nonvanishing θ anomaly there.

Three-dimensional inversions far more accurate than quasigeostrophic are now being used in weather forecasting as well as in research and development. The most accurate possible PV inversion operators are mathematically complicated because accurate balance relations $\mathbf{u} = \mathbf{u}^B$ are mathematically complicated, as discussed in the article on balanced flow. This difficulty can, however, be sidestepped using the forecast-initialization components of today's numerical data-assimilation technology.

The Quasi-westward Ratchet

The single time derivative acting on the generalized PV field in [1] and [2] exposes another fundamental point about the balanced dynamics. This point is well hidden within the equations expressing Newton's laws of motion in terms of the p , ρ , T , and $\mathbf{u}$ fields. The single time derivative shows for instance why all the different types of Rossby waves, including internal and topographic (surface θ) Rossby waves, exhibit one-way phase propagation. The Earth's rotation imposes a handedness or chirality upon the wave dynamics as seen in the rotating frame. In this regard the Rossby-wave mechanism is quite unlike classical wave mechanisms, where the governing equations always contain even numbers of time derivatives, making the propagation time-reversible.

On the global or planetary scale, P has an isentropic gradient whose sign, in a coarse-grain view, is usually set by the sign of the planetary-scale gradient in f . From the Antarctic to the Arctic, f and P go from large negative to large positive values. Planetary-scale Rossby waves feel this gradient. As a result, they exhibit westward, never eastward, phase propagation relative to the mean flow. And in all cases of Rossby waves, planetary-scale or smaller, the sense of the relative phase propagation is *quasi-westward* – meaning as if westward – defined to be such that high or predominantly high generalized PV values are on the right. Thus, for instance, topographic Rossby waves, dependent on a surface gradient in the Bretherton delta function, propagate with warm surface air on the right where 'warm' is measured by θ .

The same chirality accounts for the ratchet-like, one-way character of related processes such as the self-sharpening of jet streams and the irreversible transport of angular momentum due to the dissipation of Rossby waves in the stratosphere, producing a persistent westward or retrograde mean force there, hence the *gyroscopic pumping* – always poleward and never equatorward – that drives the global-scale stratospheric circulations and chemical transports usually discussed under the headings Brewer–Dobson circulation and wave-driven circulation.

(If a zonally symmetric mean force keeps pushing air westward, then Coriolis effects keep turning it poleward – a persistent mechanical pumping action. The best-known example is Ekman pumping, the special case in which the zonal force happens to be frictional, as in classic spindown.)

PV Mixability and Strong Jets

One of the mechanisms involved in the dissipation of Rossby waves is *wave breaking*, the irreversible deformation of otherwise-wavy PV contours. This definition of breaking is motivated by fundamental results in wave–mean interaction theory, namely the so-called nonacceleration theorems, which are corollaries of Kelvin's circulation theorem applied to initially zonal material contours.

Rossby wave breaking gives rise to the irreversible mixing of PV along the isentropic surfaces $\mathcal{S}$. This can happen on a spectacularly large scale in some cases, as in the wintertime stratospheric surf zone commonly observed. Such mixing is a strongly nonlinear phenomenon and, because it tends to be highly inhomogeneous spatially, with surf zones adjacent to

wavy PV contours, it often lies outside the scope of homogeneous turbulence (spectral cascade) theory. The idea of PV mixing does, however, explain the ubiquity of such quintessentially inhomogeneous phenomena as the strong jet streams observed in the atmosphere and oceans. The jet that flows along the poleward border of the stratospheric surf zone is just one example among many.

A strong jet, in the sense at hand, is nothing but a narrow core of concentrated isentropic gradients of P together with its induced velocity fields. The properties of PV inversion operators ensure that these induced velocity fields are always jet-like, flowing quasi-eastward, i.e., flowing with high PV on the left. For instance, in the westernmost part of [Figure 2](#) a strong jet flows southward over the Atlantic, with its core at the edge of the large colored region corresponding to high-PV stratospheric air. The jet continues around the periphery of that region past Spain toward the British Isles. Maximum wind speeds reach values of the order of 50 m s^{-1} in this case.

Once such a jet structure has formed it has a tendency to be self-sustaining or self-sharpening. The concentrated core gradients form a waveguide or duct for Rossby waves whose dispersion properties make them liable to breaking on one or both flanks of the jet, while leaving the core intact. PV mixing adjacent to the core weakens the surrounding PV gradients and strengthens the core's PV gradients, automatically sharpening or reshaping the core and the jet velocity profile. Mixing across the core is strongly inhibited, thanks to the combined effects of the shear and the core's Rossby-wave quasi-elasticity.

The inhibition applies to chemical tracers as well as to PV. Countless observations of chemical tracers verify this, going back to Edwin F. Danielsen's classic 1968 aircraft observations of nuclear bomb-test debris showing distinct isotopic signatures to either side of a strong tropopause jet core. So a strong jet core can be identified with what is sometimes called a PV barrier but more aptly an eddy-transport barrier, recognizing the complementary role of the shear in the jet flanks first noted in the doctoral thesis work of M. N. Jukes. These phenomena clearly have a role in keeping the stratosphere and troposphere chemically distinct and the tropopause sharp.

The idea that the PV is mixable along the isentropic surfaces $\mathcal{S}$ merits closer examination. In using it we are setting up an analogy with chemical mixing. How far can we push that analogy? Despite its evident power to handle some kinds of strongly nonlinear phenomena, including strong-jet formation, the analogy is not always apt because the PV is not a passive tracer. Self-organizing, dynamically active phenomena like vortex rollup, and vortex merging, illustrate that isentropic anomalies in P can, in some situations, transport themselves against mean isentropic gradients of P , contrary to the mixing idea. Furthermore, there are rotational force fields that can systematically widen the range of P values on a surface $\mathcal{S}$. If we think of isentropic anomalies in P as electric-charge anomalies, this is like pair production. Such rotational force fields include those due to dissipating gravity waves.

Nevertheless, the mixing idea seems to work well in situations such as Rossby wave breaking in which a large-scale flow advects smaller-scale PV anomalies, in a manner that becomes increasingly passive-tracer-like as the large-scale strain or deformation fields shrink the advected scales. Once this advective scale-shrinkage takes hold, it goes exponentially fast

on the timescale of the large-scale straining. The passive-tracer-like behavior is possible because PV inversion is relatively insensitive to small-scale PV anomalies.

Scenarios of PV transport along, rather than across, the moving surfaces $\mathcal{S}$ can remain valid even when [eqns \[1\] and \[2\]](#) are replaced by their diabatic and frictional generalizations. More precisely, P can be regarded as the amount per unit mass of a notional chemical substance consisting of charged particles that are permanently trapped on the moving surfaces $\mathcal{S}$. Net charge is conserved: one can have pair production and mutual annihilation, but no net creation or destruction except where a surface $\mathcal{S}$ intersects a boundary. In this picture the surfaces $\mathcal{S}$ are impermeable to the PV particles even when they are permeable to air undergoing diabatic heating or cooling – a behavior very different from that of a real chemical. The corresponding mathematical statement is sometimes called the *impermeability theorem* for PV.

The theorem is simple to prove, along with the conservation of net charge, by repeating the derivation that led to the flux-form conservation [eqn \[9\]](#) but with arbitrary diabatic heating and external forces included. This reveals first that the resulting equation is still of the form $\partial(\rho P)/\partial t + \nabla \cdot (\rho \mathbf{v} P) = 0$, i.e., that it is still a conservation equation in flux form – there are no source and sink terms – and second that the flux itself, the vector field acted on by the three-dimensional divergence operator, naturally takes a form such that it always represents zero transport across moving surfaces $\mathcal{S}$. Thus the surfaces $\mathcal{S}$ behave as if they were impermeable to the charged particles of PV substance.

Of course one can always make the surfaces $\mathcal{S}$ look permeable by adding an identically nondivergent vector field to the flux. But that is arguably a needless complication, for the reasons discussed in the paper by C. S. Bretherton and C. Schär in the Further Reading list.

It is important to remember when using the analogy with chemicals that P is the amount of PV substance or PV charge per unit mass. It is the chemical mixing ratio, so called, to which P is analogous, not the amount per unit volume. Clearly, an inert chemical lacking sources or sinks can be diluted or concentrated. An extreme example is the formation of tropical cyclones, in which, in terms of the foregoing picture, PV charge is advected inwards along the surfaces $\mathcal{S}$ and greatly concentrated near the center of the cyclone. Although such processes cannot create net PV charge, they can and do create strong isentropic anomalies in P , whose inversion may yield hurricane-force winds.

The Inhomogeneity of PV Mixing

Why does PV mixing have such a strong propensity to be inhomogeneous? Part of the answer has already been indicated, namely the self-organizing properties of strong jets as eddy-transport barriers. One can add that the inhomogeneity reflects not only the dispersion properties of jet-guided Rossby waves, but also, arguably, a generic positive-feedback mechanism sometimes called the 'PV Phillips effect.' It can operate at the earlier stages of self-organization. Wherever large-scale isentropic gradients of P are weakened by PV mixing, Rossby-wave quasi-elasticity is weakened, facilitating further mixing. On the borders of such a region, the gradients are strengthened

and mixing is inhibited. If shear and Rossby-waveguide ducting become important at the borders, then mixing is inhibited still further as eddy-transport barriers form.

There is yet another reason to expect PV mixing to be inhomogeneous. It is especially clear in the case of surfaces $\mathcal{S}$ that span the globe and are therefore topologically spherical, as in the stratosphere and upper troposphere (and also in the solar interior). If we extend the surface integrals in eqn [8] to the entire sphere, there is no enclosing contour Γ and we have

$$\iint_{\mathcal{S}} P \sigma \, dA = 0 \quad [16]$$

stating that on each topologically spherical $\mathcal{S}$ there are equal numbers of positively and negatively charged PV particles, regardless of whether the flow is forced, dissipating, or dissipationless. This is consistent with the charge-conservation and impermeability theorems. The integral relation [16] imposes a severe constraint on the possible evolution of the isentropic distributions of PV on each such $\mathcal{S}$, hence on the possible evolution of the flow. That constraint is enough in itself to make uniform or homogeneous mixing highly improbable, as the following argument shows.

Consider a hypothetical situation in which the mixing is uniform, as if the distribution of P on a surface $\mathcal{S}$ were subject to a uniform horizontal diffusivity. Under the constraint [16], in which σ is strictly positive, the perfectly mixed state toward which the distribution of P would then relax can only be a state in which $P = 0$ everywhere on $\mathcal{S}$. But invertibility says that the entire surface $\mathcal{S}$ would then have to be at rest relative to the stars, apart from oscillations representing imbalance such as sound waves and inertia-gravity waves. In a rapidly rotating system like the Earth's atmosphere, with strong Coriolis effects and Rossby numbers typically small, such a state of rest would be overwhelmingly improbable. It would require a redistribution of angular momentum that would not only have an implausibly large magnitude but would also need to take a very special form.

The Taylor Identity

The hypothetical situation just sketched is an implausible extreme case, but it illustrates another fundamental fact. Almost any isentropic redistribution of PV, or other modification to the PV field, will be accompanied by changes in the distribution of angular momentum.

The PV mixing associated with breaking Rossby waves is just one piece of what might be called a wave-turbulence jigsaw in which wave propagation has just as crucial a role as wave breaking, through wave-induced transport of angular momentum such as that giving rise, as already mentioned, to the gyroscopic pumping of the Brewer-Dobson and other global-scale mean circulations. A by-product is that eddy fluxes of momentum often look antifrictional, exhibiting the so-called 'negative viscosity' that was once regarded as a great enigma of atmospheric science, but is now recognized as a natural consequence of the interplay between wave generation, wave propagation, and wave breaking.

The way in which the jigsaw fits together is reflected in a central result from quasigeostrophic theory, which for

historical reasons might be called the Taylor-Charney-Stern-Bretherton-Eady-Green identity. It is traceable back to a seminal 1915 paper by G. I. Taylor that applies to the limiting case [14]. For brevity it will here be called the Taylor identity. It interrelates the eddy fluxes of momentum and PV. The standard form of the identity is for disturbances to a zonal-mean state. Using overbars and primes to denote the zonal mean and fluctuations about it, which can have arbitrary amplitude, we readily find from [15] that

$$\overline{v'q'} = \frac{1}{\rho_0} \left(\frac{\partial F}{\partial y} + \frac{\partial G}{\partial z} \right) \quad [17]$$

where

$$(F, G) = \rho_0 \left(-\overline{u'v'}, \frac{f_0 g}{N_0^2 \theta_0} \overline{v'\theta'} \right) \quad [18]$$

the so-called Eliassen-Palm (EP) flux or effective stress (minus the effective eddy momentum flux). This quantifies the Rossby-wave-induced momentum transport. Here $(u', v') = (-\partial\psi'/\partial y, \partial\psi'/\partial x)$, the eastward and northward components of $\hat{z} \times \nabla_H \psi'$, and $g\theta' = \theta_0 f_0 \partial\psi'/\partial z$. The vertical component of the EP flux is the same as the pressure-fluctuation-induced form stress defined in oceanography (sometimes less aptly called 'form drag'), the mean zonal force per unit area across an undulating stratification surface, whose vertical displacement is $-g\theta'/N_0^2\theta_0$. The Taylor identity has special importance not least because of its validity for strongly nonlinear flows, such as breaking Rossby waves. No small-amplitude assumption is needed.

For instance, in order to create the wintertime stratospheric surf zone, through PV mixing producing downgradient, i.e., negative, $\overline{v'q'}$, there needs to be a convergence of Rossby-wave activity from outside the surf zone, making the right-hand side of [17] negative as well, and reducing the angular momentum of the surf zone. An exquisitely precise illustration of how everything fits together is provided by the Stewartson-Warn-Warn theory of nonlinear Rossby-wave critical layers. These are narrow surf zones and well illustrate the strong inhomogeneity of the wave-turbulence jigsaw and the typical way in which [17] is satisfied.

Synopsis

The term ‘primitive equations’ has several meanings in atmospheric science. At its most general it means the basic governing equations of atmospheric dynamics. The discussion therefore starts with these equations and goes on to present three approximate forms of them, focusing on the hydrostatic primitive equations, which is most often meant by ‘primitive equations.’ A key aspect of the approximate forms is that they are internally consistent in the sense that they have natural analogues of important conservation properties of the unapproximated equations.

Introduction

Rather confusingly, the term ‘primitive equations’ has several meanings in atmospheric science. At its most general, it denotes any theoretical or numerical formulation in which velocity components are the chosen flow variables. Newton’s Second Law of Motion relates the rate of change of momentum to the net force acting, and applying it to a (small) mass of fluid gives the momentum equation that lies at the heart of fluid dynamics. Since momentum = mass × velocity, the momentum equation is also an equation for the rate of change of the velocity of the mass of fluid. The spatial components of this vector equation are known as ‘primitive equations,’ the word ‘primitive’ being used in the sense of ‘original.’ For the horizontal flow, one alternative to a primitive description is the use of 2D vorticity and divergence as flow variables.

In a general sense, then, the primitive equations are the components of the momentum equation itself, as distinct from derived forms such as vorticity or divergence equations. The term is often extended to include the other equations needed to consistently determine the time evolution of the flow and thermodynamic fields (as required in numerical weather prediction, for example).

In a much more specific (but widespread) usage, the term ‘primitive equations’ is an abbreviation for ‘the hydrostatic primitive equations with the shallow-atmosphere approximation.’ Early computer models of the large-scale atmosphere were based on geostrophically balanced vorticity equations that do not permit gravity waves. The use of the ‘primitive equations’ was a development of the 1960s, and today most numerical weather prediction and climate simulation models are based on them. Sometimes they are integrated not in their velocity component forms, but in derived vorticity and divergence forms, and here a difficulty of terminology arises: one may hear of ‘the vorticity and divergence form of the primitive equations’ – in apparent contradiction to the definition given earlier. In this usage, ‘primitive equations’ alludes to the inclusion of gravity wave motion, the distinction being made from geostrophically balanced vorticity models in which time evolution of the divergence via a forecasting equation is not allowed and gravity waves cannot occur.

In the late 1960s, E.N. Lorenz commented with characteristic humor on the established use of the term ‘primitive

equations’: “Apparently it was thought unlikely that anyone would use the exact equations, which are more primitive than the primitive equations” (Lorenz, 1967). Nowadays, however, such “more primitive” equations are increasingly being used as the foundation of meteorological models. Accordingly, our account begins (next section) with an outline derivation of the spherical polar components of the vector momentum equation that describes motion in a rotating planetary atmosphere. In the third section, three internally consistent approximate forms are considered, of which one is the hydrostatic primitive equations (HPEs) with the shallow-atmosphere approximation. The latter are the “primitive equations” in the parlance discussed by Lorenz; for brevity we shall call them the ‘HPEs.’ The fourth section is devoted to discussion of the HPEs. Various simpler formulations (much used for theoretical exploration and numerical testing) are discussed in the final section; among the most important of these are the shallow-water equations (SWEs).

The Momentum Equation and Its Spherical Polar Components

Newton’s Second Law of Motion is the main physical basis for forecasting flow in the atmosphere and oceans. For an element of fluid, a convenient expression of it is the vector momentum equation:

$$\frac{D\mathbf{u}}{Dt} = -\frac{1}{\rho}\nabla p + \mathbf{F}. \quad [1]$$

Acceleration PGF Other forces

Here, $\mathbf{u}$ is the velocity of the element of fluid, ρ is its density, and p is pressure; per unit mass, $\mathbf{F}$ is the net force acting, except for the pressure gradient force (PGF) which is given by the term $-(1/\rho)\nabla p$, ∇ being the 3D gradient operator of mathematical physics. D/Dt is the material derivative. It gives the rate of change of its operand following the fluid element, and it is related to the local (time) derivative, $\partial/\partial t$, which gives the rate of change of the operand at a fixed point instantaneously coinciding with the element, by the identity

$$\frac{D}{Dt} = \frac{\partial}{\partial t} + (\mathbf{u} \cdot \nabla). \quad [2]$$

To use eqn [1] to forecast $\mathbf{u}$, it is necessary to know $\mathbf{F}$, ρ and p as well as the present field of $\mathbf{u}$. $\mathbf{F}$ includes gravity and friction. The need to know ρ and p draws thermodynamics and mass continuity into the problem, but here we focus on eqn [1], and assume that $\mathbf{F}$, ρ , and p are known. (The equations used to forecast ρ and p will be briefly noted later on.) The spatial components of eqn [1] are primitive equations in the general sense.

Newton's Second Law applies to velocity and its rate of change measured in an inertial (i.e., nonaccelerating) frame. Relative to a rotating frame, such as that of the Earth, a fluid element may appear to be changing its direction of motion whereas relative to an inertial frame it is not. Effects of this type are precisely allowed for by a simple transformation rule. Let D/Dt be the rate of change seen in an inertial frame, and D/Dt_Ω be the rate of change seen in a frame rotating with the Earth's angular velocity Ω ; then for any vector $\mathbf{A}$,

$$\frac{D\mathbf{A}}{Dt} = \frac{D\mathbf{A}}{Dt_\Omega} + \Omega \times \mathbf{A}. \quad [3]$$

A special and important case in which eqn [3] is transparently correct (see Figure 1) is $\mathbf{A} = \mathbf{r}$ = position vector relative to the Earth's center: the velocities $\mathbf{u}$ ($= D\mathbf{r}/Dt$) and $\mathbf{u}_\Omega$ ($= D\mathbf{r}/Dt_\Omega$) measured in the inertial and rotating frames are related by

$$\mathbf{u} = \mathbf{u}_\Omega + \Omega \times \mathbf{r}. \quad [4]$$

By setting $\mathbf{A} = \mathbf{u}$ in eqn [3] and using eqn [4] on the right-hand side, we find that

$$\frac{D\mathbf{u}}{Dt} = \frac{D\mathbf{u}_\Omega}{Dt_\Omega} + 2\Omega \times \mathbf{u}_\Omega + \Omega \times (\Omega \times \mathbf{r}). \quad [5]$$

Figure 1 Depicting the Earth's rotation vector Ω , position vector $\mathbf{r}$ of a point P , and two important associated vector products. Point P rotates with the Earth, and $\mathbf{r}$ is defined relative to its center O ; $\mathbf{i}$ is unit vector in the zonal (west $\rightarrow$ east) direction at P , whose latitude is ϕ . The perpendicular distance of P from the rotation axis is $s = |\mathbf{r}| \cos \phi$, so the velocity of P relative to the inertial frame in which O is fixed is $\mathbf{i}|\Omega|s = \mathbf{i}|\Omega||\mathbf{r}| \cos \phi = \Omega \times \mathbf{r}$. Hence the velocity, $\mathbf{u}$, relative to the inertial frame, of a fluid element that is instantaneously at P but moving relative to the Earth with velocity $\mathbf{u}_\Omega$, is simply $\mathbf{u} = \mathbf{u}_\Omega + \Omega \times \mathbf{r}$. The centrifugal force $-\Omega \times (\Omega \times \mathbf{r})$, per unit mass, acts radially outwards in the plane (containing P) perpendicular to Ω . The Coriolis force (not shown) also lies in this plane.

This equation is a great step forward because it allows us to write Newton's Second Law (eqn [1]) in terms of the velocity $\mathbf{u}_\Omega$ and the acceleration $D\mathbf{u}_\Omega/Dt_\Omega$ measured in the rotating frame:

$$\frac{D\mathbf{u}_\Omega}{Dt_\Omega} = \underbrace{-2\Omega \times \mathbf{u}_\Omega}_{\text{Coriolis}} - \underbrace{\Omega \times (\Omega \times \mathbf{r})}_{\text{Centrifugal}} - \underbrace{\frac{1}{\rho} \nabla p}_{\text{PGF}} + \underbrace{\mathbf{F}}_{\text{Other forces}}. \quad [6]$$

The Coriolis and centrifugal forces (per unit mass – a stipulation that will be taken as read from now on) are as indicated beneath eqn [6]. Their presence enables us to work – and think – in terms of quantities measured or defined relative to the rotating Earth, while still respecting Newton's laws of motion.

The Coriolis force, $-2\Omega \times \mathbf{u}_\Omega$ in eqn [6], acts in planes perpendicular to the Earth's rotation axis, and depends on the component of the relative velocity $\mathbf{u}_\Omega$ in such planes, but not on the component of $\mathbf{u}_\Omega$ parallel to the Earth's rotation axis.

The centrifugal force, $-\Omega \times (\Omega \times \mathbf{r})$ in eqn [6], also acts in planes perpendicular to the Earth's rotation axis, but depends on perpendicular distance s (see Figure 1) and not at all on $\mathbf{u}_\Omega$. It acts outwards, and can be expressed as the gradient of a scalar potential:

$$-\Omega \times (\Omega \times \mathbf{r}) = \nabla(\Omega^2 s^2/2). \quad [7]$$

The term $\mathbf{F}$ in eqn [6] consists of Newtonian gravity, which can be represented as the (down) gradient of a scalar potential, say Φ_{Newt} , and the remaining force $\mathbf{F}_{\text{Rem}}$ (mainly friction):

$$\mathbf{F} = -\nabla\Phi_{\text{Newt}} + \mathbf{F}_{\text{Rem}}. \quad [8]$$

It is usual to define apparent (or normal) gravity $-\mathbf{g}\mathbf{k} = -\nabla\Phi_{\text{App}}$ as the vector sum of Newtonian gravity and centrifugal force (as given by eqn [7]). Here, g is the magnitude of apparent gravity, $\mathbf{k}$ is unit vector in the direction of apparent vertical, and Φ_{App} is the apparent gravitational potential:

$$\begin{aligned} -\mathbf{g}\mathbf{k} &= -\nabla\Phi_{\text{Newt}} - \Omega \times (\Omega \times \mathbf{r}) = -\nabla(\Phi_{\text{Newt}} - \Omega^2 s^2/2) \\ &= -\nabla\Phi_{\text{App}}. \end{aligned} \quad [9]$$

g is the quantity measured by a pendulum or a gravity meter, and apparent vertical is the (upward) direction indicated by a plumb line – all observations being made in the frame of the rotating Earth. Equation [6] may now be written as

$$\frac{D\mathbf{u}_\Omega}{Dt_\Omega} = -2\Omega \times \mathbf{u}_\Omega - \mathbf{g}\mathbf{k} - \frac{1}{\rho} \nabla p + \mathbf{F}_{\text{Rem}}. \quad [10]$$

It is illuminating to consider orders of magnitude of some of the terms in eqn [10].

The magnitude, g , of apparent gravity varies slightly with position in the atmosphere, but its order of magnitude value is 10 m s^{-2} . At latitude ϕ (see Figure 2), the centrifugal force contribution has magnitude $\Omega^2 r \cos \phi$; its components parallel and perpendicular to Newtonian gravity are (very nearly) $\Omega^2 r \cos^2 \phi$ and $\Omega^2 r \sin \phi \cos \phi$. Taking $\Omega = 2\pi/1 \text{ day} = 7 \times 10^{-5} \text{ s}^{-1}$ and $r = 6.4 \times 10^6 \text{ m}$ gives $\Omega^2 r = 3.2 \times 10^{-2} \text{ m s}^{-2}$: the contribution of centrifugal force to apparent gravity is at least 300 times smaller than the Newtonian contribution. Similarly, the deflection of the vertical due to centrifugal effects is less than $1/300$ radians in the atmosphere (the maximum value being attained at $\pm 45^\circ$ latitude, where $\sin \phi \cos \phi$ has its extreme values).

Figure 2 A unit-mass pendulum bob B, at rest relative to the rotating Earth, is in equilibrium under Newtonian gravity, centrifugal force, and the tension in the (short) string by which it is suspended from point P at latitude ϕ . To a good approximation, the angular deflection α of the string PB from the radius OP (O = Earth's center) is given by the representation $g\alpha = \Omega^2 r \cos \phi \sin \phi$ of the balance between the meridional components of tension and centrifugal force.

An upper bound to the magnitude of the Coriolis force is $2\Omega|\mathbf{u}_\Omega|$; taking $|\mathbf{u}_\Omega| \approx 50 \text{ m s}^{-1}$ – a large value for the troposphere and stratosphere – gives $2\Omega|\mathbf{u}_\Omega| \approx 0.7 \times 10^{-2} \text{ m s}^{-2}$. The Coriolis force is thus typically much smaller even than the centrifugal force – but to neglect it would be disastrous. In planes perpendicular to apparent vertical, i.e., in horizontal planes, apparent gravity has no component; the component of the Coriolis force in this plane can be very important, with the major balance of forces being between the pressure gradient and Coriolis forces. This geostrophic balance is characteristic of extratropical weather systems having horizontal scales of 1000 km or more, and is crucial to their spatial configuration and time evolution.

Having derived eqn [10] as the rotating-frame version of the momentum equation, we drop the subscripts Ω : from now on, $\mathbf{u}$ and D/Dt signify the velocity and the rate of change as measured in the rotating system. The form we shall work with is

$$\frac{D\mathbf{u}}{Dt} = -2\boldsymbol{\Omega} \times \mathbf{u} - g\mathbf{k} - \frac{1}{\rho}\nabla p + \mathbf{F}_{\text{Rem.}} \quad [11]$$

Because of centrifugal effects, the surfaces of constant apparent gravitational potential Φ_{App} are essentially nonspherical, but – as we have noted – the contribution of centrifugal force to apparent gravity is small. The usual procedure in meteorological dynamics (Lorenz, 1967; Phillips, 1973; Gill, 1982; Holton, 1992) is (1) to separate the components of eqn [11] perpendicular and parallel to apparent vertical $\mathbf{k}$, but (2) then to treat the surfaces of constant Φ_{App} (to which $\mathbf{k}$ is perpendicular) as if they were spheres. Step (2) is known as the spherical geopotential approximation. We follow this procedure here, referring the reader to van der Toorn and Zimmerman (2008) and White et al. (2008) for further discussion and examination of spheroidal approximations (which are less restrictive and in particular allow the variation of the magnitude of gravity with latitude to be represented; this is not allowed in the spherical case since a spurious source of vorticity would be implied).

In the spherical geopotential approximation it is natural to adopt a spherical polar coordinate system. What are the components of eqn [11] in this curved, non-Cartesian system?

Figure 3 Spherical polar coordinates (λ, ϕ, r) of a point P relative to Earth's center O as origin. The local unit vector triad $\mathbf{i}, \mathbf{j}, \mathbf{k}$ and associated velocity components u, v, w are also shown.

Suppose that λ is longitude, ϕ is latitude, r is distance from the Earth's center, O , and $\mathbf{i}, \mathbf{j}$, and $\mathbf{k}$ are the local triad of unit vectors associated with λ, ϕ , and r ; see Figure 3. If the zonal, meridional, and vertical components of $\mathbf{u}$ are u, v , and w , i.e.,

$$\mathbf{u} = u\mathbf{i} + v\mathbf{j} + w\mathbf{k}, \quad [12]$$

then

$$\frac{D\mathbf{u}}{Dt} = \frac{Du}{Dt}\mathbf{i} + \frac{Dv}{Dt}\mathbf{j} + \frac{Dw}{Dt}\mathbf{k} + u\frac{D\mathbf{i}}{Dt} + v\frac{D\mathbf{j}}{Dt} + w\frac{D\mathbf{k}}{Dt}. \quad [13]$$

The terms involving the material derivatives of $\mathbf{i}, \mathbf{j}$, and $\mathbf{k}$ may be re-expressed by observing that the rotation rate, relative to the Earth, of the unit vector triad as it follows the flow, is

$$\boldsymbol{\Omega}_T = -\frac{v}{r}\mathbf{i} + \frac{u}{r}\mathbf{j} + \frac{u \tan \phi}{r}\mathbf{k}. \quad [14]$$

See Figure 4. Application of a rule similar to eqn [3] gives

$$\frac{D\mathbf{i}}{Dt} = \boldsymbol{\Omega}_T \times \mathbf{i}, \quad \frac{D\mathbf{j}}{Dt} = \boldsymbol{\Omega}_T \times \mathbf{j}, \quad \frac{D\mathbf{k}}{Dt} = \boldsymbol{\Omega}_T \times \mathbf{k}. \quad [15]$$

Hence eqn [13] can be written simply as

$$\frac{D\mathbf{u}}{Dt} = \frac{Du}{Dt}\mathbf{i} + \frac{Dv}{Dt}\mathbf{j} + \frac{Dw}{Dt}\mathbf{k} + \boldsymbol{\Omega}_T \times \mathbf{u}. \quad [16]$$

By noting that the Earth's rotation vector $\boldsymbol{\Omega}$ may be expressed as

$$\boldsymbol{\Omega} = \Omega(\mathbf{j} \cos \phi + \mathbf{k} \sin \phi), \quad [17]$$

and by using eqns [12], [14], and [16], one obtains the zonal ($\mathbf{i}$), meridional ($\mathbf{j}$), and vertical ($\mathbf{k}$) components of eqn [11] as:

$$\begin{aligned} \frac{Du}{Dt} = & -\frac{uv}{r} + \frac{uv}{r} \tan \phi + 2\Omega v \sin \phi - 2\Omega w \cos \phi \\ & - \frac{1}{\rho r \cos \phi} \frac{\partial p}{\partial \lambda} + F_\lambda, \end{aligned} \quad [18]$$

$$\frac{Dv}{Dt} = -\frac{vw}{r} - \frac{u^2}{r} \tan \phi - 2\Omega u \sin \phi - \frac{1}{\rho r} \frac{\partial p}{\partial \phi} + F_\phi, \quad [19]$$

$$\frac{Dw}{Dt} = \frac{u^2}{r} + \frac{v^2}{r} + 2\Omega u \cos \phi - g - \frac{1}{\rho} \frac{\partial p}{\partial r} + F_r. \quad [20]$$

The terms on the left-hand sides of eqns [18]–[20] are the rates of change of the velocity components. The terms quadratic in

Figure 4 (a) A meridional plane through the instantaneous position P of the unit vector triad $\mathbf{i}, \mathbf{j}, \mathbf{k}$. Displacement $v\delta t$ in time δt due to meridional motion leads to rotation of the unit vector triad through an angle $\delta\phi = \frac{v\delta t}{r}$ about the local zonal axis, and thus to a rotation rate $-\frac{v}{r}\mathbf{i}$. (b) A plane perpendicular to the Earth's rotation axis and passing through the instantaneous position P of the unit vector triad $\mathbf{i}, \mathbf{j}, \mathbf{k}$; note that $\mathbf{i}$ lies in the plane of the diagram, but $\mathbf{j}$ and $\mathbf{k}$ do not. Displacement $u\delta t$ in time δt due to zonal motion corresponds to rotation of the unit vector triad through an angle $\delta\lambda = \frac{u\delta t}{r \cos \phi}$ about the Earth's rotation axis, and thus to a rotation rate $\frac{u}{r \cos \phi}(\mathbf{j} \cos \phi + \mathbf{k} \sin \phi) = \frac{u}{r}\mathbf{j} + \frac{u \tan \phi}{r}\mathbf{k}$ (unit vector along the Earth's rotation axis being $\mathbf{j} \cos \phi + \mathbf{k} \sin \phi$).

the velocity components and having $1/r$ factors are the metric terms. They are of two types: those reflecting the intrinsic uniform curvature of a sphere (the curvature of great circles) and those – involving $\tan \phi$ – reflecting the curvature of the spherical polar coordinate system (with its circles of constant latitude, of which only the Equator is a great circle). The terms involving Ω are the Coriolis terms. They too divide into two sets: those proportional to $\Omega \sin \phi$ and those proportional to $\Omega \cos \phi$; from eqn [17], $\Omega \sin \phi$ and $\Omega \cos \phi$ are, respectively, the vertical and horizontal components of the Earth's rotation vector Ω at latitude ϕ . The vertical component equation, eqn [20], contains the entire contribution of (apparent) gravity. Next come the components of the PGF in the (λ, ϕ, r) system, and finally the components of the remaining force per unit mass: $\mathbf{F}_{\text{Rem}} = F_\lambda \mathbf{i} + F_\phi \mathbf{j} + F_r \mathbf{k}$.

In our spherical polar coordinate system (recall Figure 3), the relation eqn [2] between the material derivative D/Dt and the local time derivative $\partial/\partial t$ becomes specifically

$$\frac{D}{Dt} = \frac{\partial}{\partial t} + \frac{u}{r \cos \phi} \frac{\partial}{\partial \lambda} + \frac{v}{r} \frac{\partial}{\partial \phi} + w \frac{\partial}{\partial r}. \quad [21]$$

Equations [18]–[20] are primitive equations in the general sense discussed in the Introduction. They are subject to neither

the hydrostatic nor the shallow-atmosphere approximations, and are not to be confused with the HPEs discussed in later sections.

Various conservation properties are embodied in or implied by eqns [18]–[20]. Upon noting that $w = Dr/Dt$ and $v = rD\phi/Dt$, the zonal component eqn [18] can be written

$$\frac{D}{Dt} [(u + \Omega r \cos \phi) r \cos \phi] = -\frac{1}{\rho} \frac{\partial p}{\partial \lambda} + F_\lambda r \cos \phi. \quad [22]$$

This is a conservation law for absolute axial angular momentum; the terms on the right represent torques due to the zonal components of the PGF and other forces.

A conservation relation for the sum of kinetic and potential energy per unit mass is obtained by multiplying eqns [18]–[20] by the corresponding components of $\mathbf{u}$, adding the results, and noting eqn [9]:

$$\frac{D}{Dt} \left(\frac{1}{2} \mathbf{u}^2 + \Phi_{\text{App}} \right) = \frac{1}{\rho} \mathbf{u} \cdot \nabla p + \mathbf{u} \cdot \mathbf{F}_{\text{Rem}}. \quad [23]$$

Two further important conservation relations may be established by introducing the thermodynamic and (mass) continuity equations in the forms

$$\rho c_v \frac{DT}{Dt} = -p \nabla \cdot \mathbf{u} + \rho Q \quad \text{and} \quad \frac{D\rho}{Dt} = -\rho \nabla \cdot \mathbf{u}. \quad [24]$$

Here T is temperature, c_v is the specific heat of air at constant volume, Q is the diabatic heating rate per unit mass, and perfect gas behavior is assumed, i.e., $p = \rho RT$, R being the gas constant per unit mass of air. $\nabla \cdot \mathbf{u}$, the divergence of $\mathbf{u}$, is given by

$$\nabla \cdot \mathbf{u} \equiv \frac{1}{r^2 \cos \phi} \left[\frac{\partial u}{\partial \lambda} + \frac{\partial}{\partial \phi} (v \cos \phi) \right] + \frac{1}{r^2} \frac{\partial}{\partial r} (r^2 w). \quad [25]$$

The conservation equation for total energy (i.e., kinetic + potential + internal) is

$$\rho \frac{D}{Dt} \left(\frac{1}{2} \mathbf{u}^2 + \Phi_{\text{App}} + c_v T \right) = -\nabla \cdot (p \mathbf{u}) + \rho (Q + \mathbf{u} \cdot \mathbf{F}). \quad [26]$$

The conservation equation for potential vorticity is

$$\rho \frac{D}{Dt} \left[\frac{1}{\rho} (\mathbf{Z} \cdot \nabla \theta) \right] = \mathbf{Z} \cdot \nabla \left(\frac{D\theta}{Dt} \right) + \nabla \theta \cdot (\nabla \times \mathbf{F}). \quad [27]$$

Potential vorticity is the scalar quantity in the square brackets on the left-hand side of eqn [27], i.e., $(\mathbf{Z} \cdot \nabla \theta)/\rho$. The vector $\mathbf{Z} \equiv 2\Omega + \nabla \times \mathbf{u}$ is the absolute vorticity and θ is the potential temperature defined as

$$\theta \equiv T \left(\frac{p_{\text{ref}}}{p} \right)^{\frac{R}{c_p}}, \quad [28]$$

c_p being the specific heat of air at constant pressure, and p_{ref} a reference pressure (usually taken as 1000 hPa). In the spherical polar system

$$\mathbf{Z} = Z_\lambda \mathbf{i} + Z_\phi \mathbf{j} + Z_r \mathbf{k}, \quad [29]$$

where

$$Z_\lambda = \frac{1}{r} \left[\frac{\partial w}{\partial \phi} - \frac{\partial}{\partial r} (rv) \right], \quad [30]$$

$$Z_\phi = \frac{1}{r} \left[\frac{\partial}{\partial r} (ru) - \frac{1}{\cos \phi} \frac{\partial w}{\partial \lambda} \right] + 2\Omega \cos \phi, \quad [31]$$

$$Z_r = \frac{1}{r \cos \phi} \left[\frac{\partial v}{\partial \lambda} - \frac{\partial}{\partial \phi} (u \cos \phi) \right] + 2\Omega \sin \phi. \quad [32]$$

From eqn [27] may be deduced the conservation of the potential vorticity under conditions in which the right-hand side vanishes, in particular in flow that is frictionless ($F = 0$) and adiabatic ($D\theta/Dt = 0$, which implies $Q = 0$, since $c_p D\theta/Dt = (\theta/T)Q$).

Three Internally Consistent Approximate Models

The conservation laws for energy, angular momentum, and potential vorticity should be respected when the governing equations are being approximated. One way of ensuring this is to observe that the conservation laws stem from the Hamiltonian structure of the governing equations; making approximations within that structure will then deliver individual forecasting equations (such as the components of the momentum equation) that imply consistent approximate forms of the conservation laws. Roulstone and Brice (1995) give details of this approach, which provides a perspective on all other approaches. Here, we shall note without derivation those combinations of approximation within the components of the momentum equation that imply consistent modifications of the conservation laws.

In general, there are two distinct types of approximation: (1) of the dynamics; and (2) of the geometric framework within which the dynamics occurs. In our context, the relevant modification of the dynamics (1) is omission of the term Dw/Dt from eqn [20]; this is an approximation of hydrostatic type – useful when modeling the compressible atmosphere because it only slightly affects relevant timescales and space scales, but prevents the occurrence of computationally demanding acoustic waves having a vertical component of propagation (and minimal meteorological significance). The relevant geometric modification (2) is replacement of everyday Euclidean space, having spherical polar volume element $r^2 \cos \phi d\lambda d\phi dr$ by a (weakly) non-Euclidean, spherical-shell space having volume element $a^2 \cos \phi d\lambda d\phi dr$, where a is a constant representative value of r . This is a shallow-atmosphere approximation. In the hydrostatic and shallow-atmosphere scenario there are three consistent approximations (Staniforth, 2000; White et al., 2005).

- If the shallow-atmosphere approximation is not made, but Dw/Dt and F_r (and only these terms) are omitted from eqn [20], the quasi-hydrostatic equations described by White and Bromley (1995) result.
- If the shallow-atmosphere approximation is made, and both Dw/Dt and F_r are omitted from eqn [20], the result is the HPEs:

$$\frac{Du}{Dt} = \frac{uv}{a} \tan \phi + 2\Omega v \sin \phi - \frac{1}{\rho a \cos \phi} \frac{\partial p}{\partial \lambda} + F_\lambda, \quad [33]$$

$$\frac{Dv}{Dt} = -\frac{u^2}{a} \tan \phi - 2\Omega u \sin \phi - \frac{1}{\rho a} \frac{\partial p}{\partial \phi} + F_\phi, \quad [34]$$

$$g + \frac{1}{\rho} \frac{\partial p}{\partial z} = 0. \quad [35]$$

Here, z = height above mean sea level, and the material derivative is now given by

$$\frac{D}{Dt} = \frac{\partial}{\partial t} + \frac{u}{a \cos \phi} \frac{\partial}{\partial \lambda} + \frac{v}{a} \frac{\partial}{\partial \phi} + w \frac{\partial}{\partial z}, \quad [36]$$

with $u = a \cos \phi D\lambda/Dt$, $v = a D\phi/Dt$, and $w = Dz/Dt$. See Lorenz (1967).

- A third consistent model is obtained if the shallow-atmosphere approximation is made in eqn [20], but Dw/Dt is retained (though with the definition eqn [36] of D/Dt). This is the nonhydrostatic, shallow-atmosphere (NHS) model of Tanguay et al. (1990). Equations [33], [34], and [36] are unchanged but eqn [35] becomes

$$\frac{Dw}{Dt} = -g - \frac{1}{\rho} \frac{\partial p}{\partial z} + F_r. \quad [37]$$

Each of these three approximate models implies conservation properties for energy, angular momentum, and potential vorticity that are natural analogues of those of the unapproximated equations; details for the HPEs are given in the next section.

Comparison of eqns [33]–[35] with eqns [18]–[20] shows that a substantial number of terms have disappeared in the transition to the HPEs. An important feature of both the HPEs and the NHS equations is the absence of the Coriolis terms proportional to $\cos \phi$. The complete Coriolis force may be written (from eqn [17]) as

$$2\Omega \times \mathbf{u} = 2\Omega(\mathbf{k} \times \mathbf{u} \sin \phi + \mathbf{j} \times \mathbf{u} \cos \phi), \quad [38]$$

but the term $2\Omega \mathbf{j} \times \mathbf{u} \cos \phi$ does not survive in the HPEs and the NHS equations. This omission – sometimes referred to as the traditional approximation – amounts to a change in the direction of the Coriolis force as well as in its magnitude. Whereas the true Coriolis force acts perpendicular to the Earth's rotation axis, the shallow-atmosphere Coriolis force acts in local horizontal planes. Further, part of the true Coriolis force that acts in local horizontal planes is omitted in the shallow-atmosphere version; and at the Equator the omission amounts to neglect of the entire horizontal component of the true Coriolis force. If the Coriolis terms proportional to $\cos \phi$ are retained within a shallow-atmosphere framework, then conservation of both angular momentum and potential vorticity are compromised (White et al., 2005). The omission of these Coriolis terms is therefore regarded as part of the shallow-atmosphere approximation.

The metric terms omitted in the HPEs and the NHS model are those not involving $\tan \phi$, i.e., those representing the curvature of the sphere rather than the curvature of the spherical polar coordinate system. In the triad rotation rate Ω_T (see eqn [14]), r is replaced by a and only the vertical component remains. The geometric character of the shallow-atmosphere approximation is to neglect the curvature of great circles; the curvature of small circles (such as latitude circles except the equator) is retained, but slightly underestimated. An equivalent statement is that the divergence of the Earth's radii is neglected. Either statement emphasizes the non-Euclidean character of the shallow-atmosphere approximation; see Zdunkowski and Bott (2003), Chapter 18, for further discussion.

A further consequence of the shallow-atmosphere approximation (that therefore applies to both the HPEs and the NHS model) is that gravity is not permitted to vary with height as otherwise there would be a spurious source of divergence.

The HPEs

The HPEs consist of eqns [33] and [34] (with eqn [36]) as forecasting equations for u and v , eqn [35] as a diagnostic relation between ρ and p , and equations for forecasting ρ and p and diagnosing w . (A diagnostic equation contains no time derivatives.) The appropriate forecasting equations for ρ and p are the continuity and thermodynamic equations written as

$$\frac{D\rho}{Dt} = -\rho \nabla \cdot \mathbf{u}, \quad c_v \frac{Dp}{Dt} = -p c_p \nabla \cdot \mathbf{u} + \rho R Q. \quad [39]$$

Here, D/Dt and $\nabla \cdot \mathbf{u}$ are both shallow-atmosphere forms: eqn [36] gives D/Dt , and

$$\nabla \cdot \mathbf{u} \equiv \frac{1}{a \cos \phi} \left[\frac{\partial u}{\partial \lambda} + \frac{\partial}{\partial \phi} (v \cos \phi) \right] + \frac{\partial w}{\partial z} \quad [40]$$

is recognizable as the shallow-atmosphere version of eqn [25].

The need for diagnostic calculation of w (which contributes to $\nabla \cdot \mathbf{u}$ via eqn [40], and also appears in the material derivative eqn [36]) arises because the prognostic equation eqn [20] (or eqn [37]) for w has been replaced by the diagnostic equation eqn [35] of hydrostatic balance. An expression for w (in terms of u , v , ρ , and p , their derivatives and certain integrals) may be obtained from the condition that the two eqns [39] always forecast values of ρ and p that satisfy eqn [35]. That expression, derived (before 1922) by L.F. Richardson and known as Richardson's equation, is not given here. In physical terms, w adopts the configuration that maintains hydrostatic balance as the fields of u , v , ρ , and p evolve in time; see White (2002).

Calculating w complicates the use of the HPEs in numerical time integration. The compensating advantage (as already noted) is that the omission of Dw/Dt prevents the occurrence of acoustic waves that have a vertical component of propagation. Such acoustic waves are the main mode of motion permitted by the unapproximated equations (as applied to a perfect gas) but not by the HPEs. Lamb waves – horizontally propagating compressibility waves – are permitted by the HPEs, but may or may not be present, depending on the boundary conditions applied in the vertical. Rossby (planetary) waves are present, as are gravity waves modified by rotation; both external and internal types are permitted. A range of special equatorial modes is also present (see Gill, 1982). All of these modes of motion are to some extent modified by the hydrostatic approximation, but only short gravity waves significantly so.

Temperature T may be found at any time from the perfect gas equation $p = \rho RT$, and from it (via eqn [28]) the potential temperature θ . Different forms of the HPEs may be derived by using T , θ or specific volume $\alpha (=1/\rho)$ as forecasting quantities rather than ρ and p .

What are the conditions for applicability of the HPEs? The replacement of r by a requires that the depth of the atmosphere should be small compared to the Earth's mean radius (≈ 6370 km). Since 90% of the mass of the atmosphere lies

below 17 km, this requirement is well satisfied. Other conditions relate to the terms omitted from the original component equations. Scale analysis (White and Bromley, 1995) suggests that the Coriolis terms in $\cos \phi$ are negligible (in comparison with terms retained in the HPEs) if $2\Omega H \cos \phi / U \ll 1$, H being a height scale of the motion and U a typical horizontal flow speed; substituting representative values gives $2\Omega H / U \approx 10^{-1}$. Linearized adiabatic analyses suggest that the $\cos \phi$ Coriolis terms are negligible if $2\Omega \ll N$, where $N \equiv [(g/\theta)d\theta/dz]^{1/2}$ is the buoyancy frequency. Since $2\Omega \sim 10^{-4} \text{ s}^{-1}$ and $N \sim 10^{-2} \text{ s}^{-1}$, this condition, typically, is well satisfied at least above the planetary boundary layer.

More tangibly, the term $-2\Omega w \cos \phi$ in eqn [18] describes the conservation of absolute axial angular momentum in axisymmetric vertical motion, which can lead to changes of zonal flow speed of up to 2 m s^{-1} over the depth of the tropical troposphere; this effect is not described by the HPEs. The omission of the $\cos \phi$ Coriolis terms is the most striking approximation of the HPEs as applied to large-scale motion – particularly diabatically forced motion in the tropics – but there is, as yet, no evidence to suggest that their inclusion makes significant difference in numerical weather prediction and climate simulation. Their inclusion has, however, been found to have a significant effect on the depth of the neutrally stratified, planetary boundary layer as modeled by large-eddy simulations (Mason and Thomson, 1987). The advantages of retaining the $\cos \phi$ Coriolis terms (either by using eqns [18]–[20] or the quasi-hydrostatic model noted in Section Three Internally Consistent Approximate Models) are that justification for their exclusion does not then have to be supplied, that the Coriolis force is accurately and completely represented, and that the shallow-atmosphere approximation is simultaneously abandoned; the geometric framework becomes (once again) Euclidean, and intuition based on everyday experience of 3D space can be safely exercised.

The criterion most often quoted for the neglect of the term Dw/Dt is $H \ll L$, L being a horizontal length scale of the motion; this is well satisfied by many flow phenomena, for example midlatitude weather systems, for which $H/L \sim 10^{-2}$. A more discriminating criterion (which covers cases in which $H/L \sim 1$, but the neglect of Dw/Dt is still a good approximation) is that the Lagrangian timescale τ of the motion should be large compared with that of vertical buoyancy oscillations (which are essentially nonhydrostatic): $\tau \gg N^{-1}$. Thus the HPEs require for their validity that N should be large compared with some threshold value, both as regards the $\cos \phi$ Coriolis terms and Dw/Dt ; they do not remain valid as $N \rightarrow 0$. This situation makes use of the original eqns [18]–[20] attractive and was a motivation for the inclusion of a representation of the $\cos \phi$ Coriolis terms in the numerical simulations of the neutrally stratified planetary boundary layer by Mason and Thomson (1987).

The horizontal component eqns [33] and [34] of the HPEs may be written in various useful alternative forms. A vector form, in terms of the horizontal flow $\mathbf{v} = (u, v, 0)$ is

$$\frac{\partial \mathbf{v}}{\partial t} = -\nabla_z \left(\frac{\mathbf{v}^2}{2} \right) - w \frac{\partial \mathbf{v}}{\partial z} - (\zeta + f) \mathbf{k} \times \mathbf{v} - \frac{1}{\rho} \nabla_z p + \mathbf{F}_h. \quad [41]$$

Here $f \equiv 2\Omega \sin \phi$ (and is customarily called the Coriolis parameter), $\mathbf{F}_h \equiv F_\lambda \mathbf{i} + F_\phi \mathbf{j}$, and the horizontal gradient

operator, ∇_z , and the vertical component of vorticity, ζ , are given by

$$\nabla_z \equiv \left(\frac{1}{a \cos \phi} \frac{\partial}{\partial \lambda}, \frac{1}{a} \frac{\partial}{\partial \phi}, 0 \right), \quad [42]$$

$$\zeta \equiv \frac{1}{a \cos \phi} \left[\frac{\partial v}{\partial \lambda} - \frac{\partial}{\partial \phi} (u \cos \phi) \right]. \quad [43]$$

Forecasting equations for the vorticity, ζ (see eqn [43]), and the horizontal divergence, δ , given by

$$\delta = \nabla_z \cdot \mathbf{v} \equiv \frac{1}{a \cos \phi} \left[\frac{\partial u}{\partial \lambda} + \frac{\partial}{\partial \phi} (v \cos \phi) \right], \quad [44]$$

may be obtained by taking the horizontal curl and divergence of eqn [41]. The resulting equations (not given) are the vorticity-divergence forms of the HPEs. Other useful forms of eqns [33] and [34] involve $u \cos \phi$ and $v \cos \phi$ under the material derivative; these quantities have better transformation properties on the sphere than u and v have.

The HPEs imply good conservation properties in terms of the shallow-atmosphere versions eqn [36] of D/Dt and the ∇ operator (see, e.g., eqn [40]). Axial angular momentum conservation follows from the zonal component eqn [33]:

$$\frac{D}{Dt} [(u + \Omega a \cos \phi) a \cos \phi] = -\frac{1}{\rho} \frac{\partial p}{\partial \lambda} + F_\lambda a \cos \phi \quad [45]$$

(cf eqn [22]). Total energy (kinetic + potential + internal) obeys

$$\rho \frac{D}{Dt} \left(\frac{1}{2} \mathbf{v}^2 + gz + c_v T \right) = -\nabla \cdot (p \mathbf{u}) + \rho (Q + \mathbf{v} \cdot \mathbf{F}), \quad [46]$$

(cf eqn [26]) and the potential vorticity law is

$$\rho \frac{D}{Dt} \left(\frac{\mathbf{Z} \cdot \nabla \theta}{\rho} \right) = \mathbf{Z} \cdot \nabla \left(\frac{D\theta}{Dt} \right) + \rho \nabla \theta \cdot (\nabla \times \mathbf{F}_h), \quad [47]$$

(cf eqn [27]). In eqn [47], $\mathbf{Z}$ is the 3D HPE shallow-atmosphere absolute vorticity vector given by

$$\mathbf{Z} = -\frac{\partial v}{\partial z} \mathbf{i} + \frac{\partial u}{\partial z} \mathbf{j} + (f + \zeta) \mathbf{k}. \quad [48]$$

(cf eqns [29]–[32]). From eqn [47] follows the conservation of the HPE potential vorticity, $(\mathbf{Z} \cdot \nabla \theta)/\rho$, in flow that is frictionless ($\mathbf{F}_h = 0$) and adiabatic ($D\theta/Dt = 0$). Neither the HPE specific kinetic energy $\frac{1}{2} \mathbf{v}^2$ nor the horizontal components of the HPE absolute vorticity $\mathbf{Z}$ involves the vertical velocity w ; $\mathbf{Z}$ also omits the contribution $2\Omega \cos \phi \mathbf{j}$ of the horizontal component of the Earth's rotation to the true absolute vorticity.

The consequences of eqn [35] are extensive and profound. As already noted, acoustic waves having a vertical component of propagation do not occur, and the vertical velocity w must be found diagnostically. In addition, ρ can be eliminated in favor of $\partial p / \partial z$ if desired. More important, pressure becomes an attractive choice of vertical coordinate, a 1:1 correspondence between p and z being assured because ρ (and g) are necessarily positive quantities.

Use of pressure as vertical coordinate simplifies the HPEs when considered purely as a set of partial differential equations (independently of spatial boundary conditions). The horizontal gradient term $(1/\rho) \nabla_z p$ in eqn [41] becomes $\nabla_p (gz)$, where ∇_p is the horizontal gradient operator on pressure

surfaces and z (now a dependent variable) is the height of a pressure surface at any time and horizontal location. The major simplification, however, is that the continuity equation, eqn [39], becomes a simple diagnostic relationship:

$$\nabla_p \cdot \mathbf{v} + \frac{\partial \omega}{\partial p} = 0. \quad [49]$$

Here, $\omega \equiv Dp/Dt$ is the pressure-coordinate 'vertical velocity' and

$$\nabla_p \cdot \mathbf{v} \equiv \frac{1}{a \cos \phi} \left[\frac{\partial}{\partial \lambda} \bigg|_p u + \frac{\partial}{\partial \phi} \bigg|_p (v \cos \phi) \right]. \quad [50]$$

The material derivative eqn [36] is given in 'pressure coordinates' by

$$\frac{D}{Dt} = \frac{\partial}{\partial t} \bigg|_p + \frac{u}{a \cos \phi} \frac{\partial}{\partial \lambda} \bigg|_p + \frac{v}{a} \frac{\partial}{\partial \phi} \bigg|_p + \omega \frac{\partial}{\partial p}, \quad [51]$$

and involves ω rather than w . In eqns [50] and [51], all differentiations with respect to λ , ϕ , and t are taken at constant pressure, and the derivative $\partial/\partial p$ is taken at constant λ , ϕ , and t .

From eqn [49], using appropriate boundary conditions, the 'vertical velocity' ω may be found by integration over p ; the procedure parallels the derivation of Richardson's equation in height coordinates (see above), but the functions involved are fewer and simpler. Against this must be weighed the complication that pressure varies in space and time (even on horizontal surfaces); consequently, before the integration over p to determine ω can be started, computational effort has to be expended in finding the pressure, p_s , at the Earth's surface.

In the pressure-coordinate system, the thermodynamic equation is conveniently rewritten as a forecasting equation for temperature T :

$$\frac{DT}{Dt} = \frac{RT}{\rho c_p} \omega + \frac{Q}{c_p}. \quad [52]$$

In broad outline, the time integration procedure (as applied to appropriately discretized forms of the equations, and assuming required initial values are known) is as follows:

1. forecast u , v , and T using eqns [33], [34], and [52];
2. find surface pressure p_s and then ω from eqn [49];
3. find z from p_s , the terrain height z_s , and the hydrostatic equation, eqn [35], in the form

$$\frac{\partial z}{\partial p} = -\frac{gp}{RT}; \quad [53]$$

4. repeat (1)–(3) until the desired forecast time or simulation length has been attained.

The complications involved in step (2) of this procedure (see earlier remarks) are significantly reduced if, instead of p , a terrain-following coordinate such as $\sigma = p/p_s$ is used; see Figure 5 for orientation, and Haltiner and Williams (1981) for mathematical formulation. As well as p and σ , many other quantities may be used as vertical coordinates; examples are θ and hybrids that behave as p , σ , and θ (say) in different height

Figure 5 Vertical sections through mountainous terrain showing the behavior of vertical coordinate surfaces of systems which (a) are, (b) are not, terrain-following. Intersection of coordinate surfaces with the Earth's surface, as seen in (b), complicates the construction and operation of numerical models based on non-terrain-following systems. In most respects, the use of terrain-following coordinate systems, as shown in (a), is more convenient.

ranges. See Kasahara (1974), Simmons and Burridge (1981), and Zhu et al. (1992). In all cases, the equations (before discretization) are exact transforms of the HPEs in height coordinates.

Further Simplifications

As is essential for numerical weather prediction and climate simulation, the HPEs treat the 3D structure of the atmosphere's flow and thermodynamic fields. A simpler set of 2D equations, useful as a theoretical and numerical test bed, is the SWEs. These describe the depth (h) variations and depth-independent motion of a shallow layer of incompressible fluid covering a gravitating sphere. The (horizontal) momentum components of the SWEs are

$$\frac{Du}{Dt} = \frac{uv}{a} \tan \phi + fv - \frac{g}{a \cos \phi} \frac{\partial h}{\partial \lambda} + F_\lambda, \quad [54]$$

$$\frac{Dv}{Dt} = -\frac{u^2}{a} \tan \phi - fu - \frac{g}{a \partial \phi} \frac{\partial h}{\partial \phi} + F_\phi, \quad [55]$$

and the (depth-integrated) continuity equation is

$$\frac{Dh}{Dt} = -\frac{h}{a \cos \phi} \left(\frac{\partial u}{\partial \lambda} + \frac{\partial}{\partial \phi} (v \cos \phi) \right). \quad [56]$$

Figure 6 A zone between latitudes $\phi = \phi_0 \pm \Delta\phi$ on a sphere of radius a (a), and a Cartesian 'channel' domain corresponding to it (b). In the channel domain, cyclic conditions in x are applied; boundary conditions in y are more problematic, since no physical boundaries exist at $\phi = \phi_0 \pm \Delta\phi$ in the atmosphere. The channel is usually not a precise mapping of the zone, but is considered as a crude approximation to it. Adopted widths L_y are often somewhat greater than is strictly justifiable, the objective being to obtain theoretical or numerical indications of atmospheric behavior that may then be pursued in more realistic geometrical environments.

In eqns [54]–[56], the material derivative is simply

$$\frac{D}{Dt} = \frac{\partial}{\partial t} + \frac{u}{a \cos \phi} \frac{\partial}{\partial \lambda} + \frac{v}{a} \frac{\partial}{\partial \phi}. \quad [57]$$

Equations [54] and [55] are similar to the horizontal components of the HPEs (especially the p -coordinate forms) except that no vertical variations are allowed; similarly, eqn [56] is comparable to the HPE continuity equation, eqn [39], with vertical variations disallowed.

So far as they are able, the SWEs mimic the rich variety of wave types that are found in the HPEs. They describe depth-independent (barotropic) Rossby waves and surface gravity waves, and have special tropical modes; indeed, from the time of Laplace, studies of the SWEs have helped to elucidate the physics of wave motion in the atmosphere and oceans.

When qualitative rather than quantitative results are sought (as in exploratory theoretical work and numerical testing) the HPEs and the SWEs are conveniently used in simplified forms that neglect the metric terms and replace the spherical polar geometric factors by Cartesian ones. For example, the SWEs may be used in the following forms:

$$\left(\frac{\partial}{\partial t} + u \frac{\partial}{\partial x} + v \frac{\partial}{\partial y} \right) u = fv - g \frac{\partial h}{\partial x} + F_x, \quad [58]$$

$$\left(\frac{\partial}{\partial t} + u \frac{\partial}{\partial x} + v \frac{\partial}{\partial y} \right) v = -fu - g \frac{\partial h}{\partial y} + F_y, \quad [59]$$

$$\left(\frac{\partial}{\partial t} + u \frac{\partial}{\partial x} + v \frac{\partial}{\partial y}\right)h = -h \left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}\right). \quad [60]$$

Here, $x \equiv a\lambda \cos \phi_0$ and $y \equiv a(\phi - \phi_0)$ are zonal and meridional coordinates in a Cartesian plane; as shown in [Figure 6](#), the domain represents a neighborhood of latitude ϕ_0 and the full 2π range of longitude in a ‘channel model.’ The latitude variation of the Coriolis parameter f is neglected in the ‘ f -plane’ approximation. In the ‘ β -plane’ approximation, f is represented as a linear function of y : $f = 2\Omega \sin \phi_0 + 2\Omega(\phi - \phi_0) \cos \phi_0 \equiv f_0 + \beta y$. An ‘equatorial β -plane’ has $\phi_0 = 0$ and hence $f_0 = 0$, $\beta = 2\Omega/a$.

Cartesian forms are also locally valid in a naïve tangent plane approximation for motions whose scale is very small compared with the Earth’s radius. Interestingly, the neglect of curvature in all these Cartesian approximations restores the underlying geometry to Euclidean form; only through the shallow-atmosphere approximation, as represented in spherical geometry in the HPEs (see third section, above) did non-Euclidean effects enter our account.

Quasigeostrophic Theory

HC Davies and H Wernli, Institute for Atmospheric and Climate Science, Swiss Federal Institute of Technology (ETH), Zürich, Switzerland

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

Synoptic- and larger-scale atmospheric flow in the extratropics is almost geostrophic in character, indicating an approximate balance between the Coriolis and pressure gradient forces. The concept of quasigeostrophy (QG) encapsulates elegantly and simply the dynamics whereby the flow retains this character, although both the maintenance of geostrophy and the existence of other key flow features require a nongeostrophic flow component.

Consideration is given to the QG concept's observational foundation, its mathematical formulation, and the interpretation of its subtle physics. In addition, a cursory case study analysis is provided to demonstrate the essence and nature of QG dynamics and the utility of the QG perspective.

Introduction

The concept of quasigeostrophic flow is a cornerstone for the study of synoptic and larger-scale atmospheric flow in the extratropics. It is founded upon two seemingly contradictory deductions regarding the nature of such flows: the flow is observed to be almost geostrophic, and yet both the maintenance of geostrophy and the existence of other key features of synoptic weather systems require a nongeostrophic flow component.

This paradox is resolved by the concept of quasigeostrophy (QG). It is encapsulated in two simple and elegant mathematical formulations that prescribe, respectively, the evolution of the primary 'geostrophic' flow and the form of an accompanying secondary 'ageostrophic' flow that is forced by the primary field. It is the net of these two flow components that constitutes QG flow.

Here, we successively illustrate the concept's observational foundation, tabulate its mathematical formulation, and interpret its subtle physics. Finally, a cursory case study analysis is provided to demonstrate the essence and nature of QG dynamics and the utility of the QG perspective.

Foundation

Governing Equations

For synoptic-scale flow of the free atmosphere away from the Earth's surface, the conservation equations for horizontal momentum, mass, and thermodynamic energy can be written in the following approximate form:

$$D_H \mathbf{V} / Dt + w \partial \mathbf{V} / \partial z = -f(\mathbf{k} \wedge \mathbf{V}) - \nabla_H(p^* / \rho_0) \quad [1]$$

$$\nabla_H \cdot \mathbf{V} + \mathcal{L}w = 0 \quad [2]$$

$$D_H(g\theta^* / \Theta) / Dt + N^2 w = H \quad [3]$$

The corresponding approximate form for the hydrostatic relationship is given by

$$\partial(p^* / \rho_0) / \partial z = (g\theta^* / \Theta) \quad [4]$$

Here, t stands for time, and $\mathbf{k}$ is the vertical unit vector. The flow variables $(\mathbf{V}, w)$ represent, respectively, the horizontal vector velocity and the vertical velocity. The thermodynamic variables $(p, \rho, \text{ and } \theta)$ denote, respectively, the pressure, density, and

potential temperature. For the latter three variables, the zero subscript refers to a time-mean and horizontally averaged measure of the atmosphere's vertical structure, whereas the starred superscript signifies the deviation away from that mean state. In addition, ∇_H is the horizontal gradient operator, $f = 2\Omega \sin \varphi$ is the Coriolis parameter (with Ω denoting the Earth's angular velocity and φ the latitude), N is the mean state buoyancy frequency such that $N^2 = g d(\ln \theta_0) / dz$, Θ is a reference potential temperature, and H is the net diabatic heating rate. Also, $\mathcal{L}$ is a differential operator, such that $\mathcal{L}A = (1/\rho_0) \partial(\rho_0 A) / \partial z$, and in the incompressible limit this reduces to $\mathcal{L}A = \partial A / \partial z$. Finally, D_H / Dt is the rate of change following the horizontal motion of an air parcel, and it is related to the local rate of change at a fixed point by the following expression:

$$D_H / Dt = \{ \partial / \partial t + \mathbf{V} \cdot \nabla_H \} \quad [5]$$

The momentum equation (eqn [1]) states that a change in the horizontal velocity of an air parcel results essentially from an imbalance between two forces: the Coriolis force due to the Earth's rotation and the horizontal pressure gradient force. The approximated equation for mass continuity (eqn [2]) states that expansion in the horizontal cross-section of an air parcel induced by divergence of the horizontal wind field is compensated by a vertical contraction accomplished by the vertical motion. The thermodynamic equation (eqn [3]) states that a change in the potential temperature of an air parcel following the horizontal motion can be induced in two ways: a vertical transport of the potential temperature, and a diabatic contribution that is the net of contributions related primarily to latent heat release, radiative transfer, and turbulent diffusion.

Character of Geostrophic Flow

For synoptic- and larger-scale atmospheric flow, the dominant terms in the horizontal momentum equation (eqn [1]) are usually the Coriolis term and the pressure gradient. If an exact balance prevailed between these two forces, then it would follow that

$$f(\mathbf{k} \wedge \mathbf{V}) = -\nabla_H(p^* / \rho_0)$$

In such a state of so-called geostrophic balance, the flow would be aligned perpendicular to the horizontal pressure gradient (i.e., along the contours of constant pressure), and its

strength would be proportional to the pressure gradient. Alternatively, for a given pressure field, this equation can be used to define a 'geostrophic flow,' and the difference between it and the observed flow would provide a measure of the departure from geostrophy.

Assuming for the moment a single value ($f = f_0$) for the Coriolis parameter, then the equation for the geostrophic flow field ($\mathbf{V} = \mathbf{V}_G$) and the hydrostatic relationship eqn [4] can be written in the following compact form:

$$\mathbf{V}_G = \mathbf{k} \wedge \nabla_H \psi, \quad \text{and} \quad g\theta^*/\Theta = f_0 \partial \psi / \partial z \quad [6]$$

where $\psi = (p^*/f_0\rho_0)$ is referred to as the geostrophic stream function. A striking inference is that the spatial distribution of ψ (or, equivalently, p^*) defines both the geostrophic velocity field and the potential temperature field.

There are other notable features to geostrophic flow. The geostrophic vorticity ζ_G and geostrophic divergence D_G are given, respectively, by

$$\zeta_G = (\nabla_H \wedge \mathbf{V}_G) = \nabla_H^2 \psi \quad [7]$$

$$D_G = (\nabla_H \cdot \mathbf{V}_G) = 0 \quad [8]$$

Also, from eqns [6] and [7], the vertical variations of the geostrophic flow and of the vorticity are given by

$$\partial \mathbf{V}_G / \partial z = (g/f_0\Theta)(\mathbf{k} \wedge \nabla_H \theta^*) \quad [9]$$

$$\partial \zeta_G / \partial z = (g/f_0\Theta) \nabla_H^2 \theta^* \quad [10]$$

A simple interpretation can be given to eqns [7] and [10] by noting that, in the neighborhood of a region where the scalar variable A has a local extremum,

$$\nabla_H^2 A \propto -A$$

Thus, eqn [7] indicates that the geostrophic vorticity is positive in a localized region of low pressure (and vice versa), and eqn [10] that the vertical gradient of vorticity is positive in a localized region of colder air (and vice versa). Equation [8] equates the horizontal divergence of the geostrophic flow to zero, and thereby emphasizes the purely horizontal character of geostrophic flow. Equation [9] is a thermal wind relationship indicating that the vertical variation of the geostrophic wind is aligned such that the potential temperature is relatively cold (warm) on its left (right) flank.

Nature of Synoptic-Scale Flow

Figures 1 and 2 indicate the extent to which the atmosphere's synoptic-scale flow both conforms to the geostrophic interrelationships (i.e., eqns [6–10]) and is consistent with the aforementioned physical interpretations. The displayed synoptic charts are for a portion of the Atlantic sector and are valid at 1200 UTC 31 December 2006. At this time, an incipient low-pressure system (i.e., an extratropical cyclone) was developing on a surface baroclinic zone located southeast of Newfoundland, while aloft a deepening trough was approaching the low.

Figure 1(a) and 1(c) shows the geopotential height and velocity fields on the 300 and 700 hPa levels, respectively. The displayed patterns are in broad accord with the geostrophic relationship (eqn [6]), with the flow aligned approximately along the iso-height contours and with its strength roughly

inversely proportional to the local contour spacing. However, significant departures from geostrophy (white contours) are evident. These regions tend to be smaller in spatial scale and irregular in structure, but there are some coherent features, for instance those associated with strong flow curvature located within and at the base of the major troughs at the upper and lower levels.

Figure 1(b) shows the wind difference between the 700 and 300 hPa levels plus the isentropes at the intermediate level of 500 hPa. In this case, the patterns are in broad qualitative accord with the thermal wind relationship (eqn [9]), with the wind difference field aligned approximately along the isentropes.

Figure 2(a) and 2(c) displays the relative vorticity and the divergence fields on, respectively, the 300 and 700 hPa surfaces. First, consider the vorticity patterns. These patterns, viewed in conjunction with the height fields displayed in Figure 1(a) and 1(c), are broadly consistent with the inverse relationship between the vorticity and pressure fields (eqn [7]). In particular at the 300 hPa level, there is an enhanced band of vorticity linked to the trough in the height field, and at the 700 hPa level, there is a maximum of vorticity in the vicinity of the cyclone.

Again, comparison of the vorticity patterns in Figure 2(a) with the contemporaneous potential temperature field at 500 hPa (Figure 1(b)) indicates that, in qualitative accord with eqn [10], the increase of the vorticity with height beneath the aforementioned strong band of vorticity at the upper level corresponds to a relatively colder region in the midtroposphere.

Comparison of the vorticity and divergence fields in Figure 2(a) and 2(c) suggests that, in accord with eqns [7] and [8], the amplitude of the divergence fields is indeed significantly less than that of the counterpart vorticity fields. Nevertheless, the divergence fields are decidedly nonzero, and this is indicative of a nongeostrophic flow component. Again, the divergence fields tend to be smaller in scale and fragmented in structure. There is a distinct and coherent region of divergence at the upper level ahead of the trough over the Atlantic Ocean. Likewise, at lower levels, there are patches of strong convergence in the neighborhood of the Low, and moreover the aforementioned region of divergence aloft surmounts a fragmented band of convergence at a lower level that is aligned ahead of the cold front. This reversal in sign with height connotes ascent between the 700 and 300 hPa levels (see eqn [2]), and it is thereby consistent with the patterns of the mid-tropospheric vertical velocity field and surface rainfall displayed in Figure 2(b). In assessing this qualitative agreement between vertical velocity and rainfall, note that the former quantity is instantaneous, whereas the latter is integrated over the preceding 6 h.

Thus, inspection of the synoptic-scale fields confirms the flow's predominantly 'geostrophic' character, but it also points to the existence of more fragmented but nevertheless coherent 'nongeostrophic' flow features. This duality is important on two counts. First, a synoptic weather system characterized by a purely geostrophic flow is not compatible with the occurrence of cloud and rain because these processes generally require a nonzero vertical velocity field. Indeed, the precipitation patterns displayed in Figure 2(b) correspond well with the vertical velocity and divergence fields. Second, there is an enigma associated with the sustainment of the geostrophic nature of the atmospheric fields. Equations [1] and [3] are

Figure 1 Synoptic charts for a portion of the North Atlantic valid at 12 UTC 31 December 2006, at which time a low-pressure system was developing south of Newfoundland. The upper and lower panels are for, respectively, the 300 and 700 hPa pressure surfaces (i.e., altitudes of ~8 and 3 km), and they indicate the flow pattern (see the representative wind vector in units of m s^{-1}) and the geopotential height field (a proxy for the pressure distribution at an appropriate altitude), plus the departure from geostrophy (thin and bold white contours corresponding to 20 and 30% deviations from geostrophy). The middle panel depicts the potential temperature field at the 500 hPa level and the thermal wind field vectors corresponding to $\{\mathbf{v}(300) - \mathbf{v}(700)\}$.

Figure 2 Counterpart of Figure 1, but now displaying in the upper and lower panels the relative vorticity fields and the horizontal divergence fields (contour intervals in units of 10^{-5} s^{-1}). In the upper panel, solid (dashed) contours denote divergence (convergence), with the converse applying for the lower panel. The middle panel depicts the precipitation accumulated during the previous 6 h and the vertical velocity field on the 500 hPa surface (contours for $\pm 0.3, 1$, and 2 Pa s^{-1} , with dashed lines for negative values indicating ascending motion).

independent prediction equations for the horizontal velocity $\mathbf{V}$ and the potential temperature θ , and hence they do not necessarily ensure that geostrophy is maintained in time. These two issues serve to prompt, and indeed are central to, the concept of QG.

Mathematical Formulation

Flow Subdivision

The concept of QG enables the dynamics of synoptic-scale flow to be viewed from a simple and self-consistent perspective that condenses to an elegant mathematical formulation.

In the QG framework, the three-dimensional atmospheric flow field ($\mathbf{U}$) is conceived to comprise two components: a primary, purely horizontal geostrophic component $\mathbf{V}_G$, defined by eqn [6]; and a secondary, three-dimensional ageostrophic component ($\mathbf{V}_{AG}, w$):

$$\mathbf{U} = (\mathbf{V}_G, 0) + (\mathbf{V}_{AG}, w) \quad [11]$$

The ageostrophic component is deemed to be the additional velocity field required to maintain the flow in an almost-geostrophic (i.e., QG) state (discussed further in this article).

The concept itself is formulated here in the idealized setting of flow taking place on and above a plane that is tangential to the Earth's surface at a specified latitude ($\varphi = \varphi_0$) located in the extratropics. On this surface, commonly referred to as the β -plane, the Coriolis parameter (f) is taken to vary linearly in the y -direction (i.e., poleward in the Northern Hemisphere) and is represented by

$$f = f_0 + \beta y \quad [12]$$

where $(f_0, \beta) = (2\Omega \sin \varphi_0, 2\Omega \cos \varphi_0/a)$, with a denoting the Earth's radius.

A systematic introduction of the foregoing flow subdivision into eqns [1–4] in a manner consistent with the primacy of the geostrophic flow component results in the following quasi-geostrophic set of equations:

$$D_G \mathbf{V}_G / Dt = \mathbf{G} \quad [13]$$

$$\text{with } \mathbf{G} = \boxed{-f_0(\mathbf{k} \wedge \mathbf{V}_{AG})} - \beta \gamma(\mathbf{k} \wedge \mathbf{V}_G)$$

$$\boxed{\nabla_H \cdot \mathbf{V}_{AG} + \mathcal{L}w = 0} \quad [14]$$

$$D_G b / Dt + \boxed{N^2 w} = H \quad [15]$$

Here, D_G/Dt refers to the rate of change following the horizontal geostrophic motion, $\mathbf{G}$ is a reduced form for the sum of the Coriolis and pressure gradient forces of eqn [1], and the buoyancy (b) equates to $b = (g\theta^*/\Theta)$. For later use, we note that the boxed terms in eqns [13–15] include contributions from the ageostrophic flow.

In the next two sub-sections, eqns [6, 13–15] are recast into two quasi-independent subsets for, respectively, the geostrophic and the ageostrophic flow.

Prognostic Geostrophic Equations

A set of equations governing the evolution of the geostrophic flow component is derivable from eqns [6, 13–15]. There is

a prognostic equation for the so-called QG potential vorticity, q , that takes the following form:

$$D_G \{q + \beta y\} / Dt = f_0 \mathcal{L}(H/N^2) \quad [16]$$

with q given by

$$q = [\nabla_H^2 \psi + f_0^2 \mathcal{L}\{(1/N^2) \partial \psi / \partial z\}] \quad [17]$$

Likewise, there is a prognostic equation for the surface potential temperature of the following form:

$$D_G(b)/Dt_{z=0} = H_{z=0} \quad [18]$$

And, furthermore, $b (= f_0 \partial \psi / \partial z)$ is merely a function of ψ , the geostrophic stream function.

Thus, these equations prescribe the space–time evolution of q in the interior (eqn [16]) and b at the surface (eqn [18]). They have an initial-boundary value character in that

1. at an initial time, their solution requires the specification of ψ to permit the forward integration of eqns [16] and [18] to yield the subsequent distribution of q in the interior and $\partial \psi / \partial z$ at the surface; and
2. the boundary specification of $\partial \psi / \partial z$ at the surface is required at all subsequent times to permit the inversion of the elliptic eqn [17] to obtain the spatial distribution of ψ .

Note, moreover, that this set of equations is self-contained provided H is known externally or is specifiable in terms of the geostrophic state.

It follows that the evolution of synoptic-scale atmospheric flow is captured to the first order by a remarkably simple and mathematically elegant simplification of the far more complex governing equations.

Diagnostic Ageostrophic Equation

Equations [13–15] can be manipulated to show that the vertical component, w , of the ageostrophic flow satisfies the following elliptic equation:

$$N^2 \nabla_H^2 w + f_0^2 \partial \{\mathcal{L}w\} / \partial z = F + f_0 \beta \partial \mathbf{V}_G / \partial z + \nabla_H^2 H \quad [19]$$

with F , a known function (discussed later in this article) of the geostrophic stream function.

In effect, w is a diagnostic variable whose spatial distribution at any specified time can be determined by inverting eqn [19] given the contemporaneous distribution of the geostrophic stream function ψ and H in the interior and applying the bottom boundary condition $w_{z=0} = 0$. This diagnostic equation is customarily referred to as the ‘omega equation.’

Physical Interpretation

Relationship between the Geostrophic and Ageostrophic Flow

The physical interpretation of QG flow hinges upon the nature of the relationship between the geostrophic and ageostrophic flow components. The subtlety of this relationship can be exemplified in two ways.

First, in their raw form, the QG eqns [13–15] point to a direct influence of the ageostrophic flow (the boxed ageostrophic terms) upon the evolution of the geostrophic velocity and the potential temperature fields. However, this seemingly ostensible link is deceptive. In particular, the form of the

prognostic relationships (eqns [16–18]) demonstrates that the evolution of the QG potential vorticity, q , depends upon only the geostrophic flow itself and is independent of the ageostrophic flow.

Second, deriving separately the rate of change of the two terms in the thermal wind relationship (eqn [9]) yields

$$D_G\{\partial \mathbf{V}_G/\partial z\}/Dt = -f_0 \mathbf{R} - \{\mathbf{k} \wedge (f_0 \partial \mathbf{V}_{AG}/\partial z + \beta \gamma \partial \mathbf{V}_G/\partial z)\} \quad [20]$$

$$D_G\{\mathbf{k} \wedge \nabla_H b\}/Dt = +f_0 \mathbf{R} - \{\mathbf{k} \wedge \nabla_H (N^2 w - H)\} \quad [21]$$

with $\mathbf{R} = [\partial \mathbf{V}_G/\partial z \cdot \nabla_H] \mathbf{V}_G$

so that $\mathbf{R}$ denotes the rate of change of the geostrophic flow along the thermal wind vector.

It follows that the rate of change of the vertical shear of the geostrophic wind (eqn [20]) and the baroclinicity (eqn [21]) are influenced by both the geostrophic flow itself and the ageostrophic flow. However, the influence of the geostrophic $\mathbf{R}$ term upon the shear and baroclinicity terms is equal and opposite. In effect, the geostrophic component acts to destroy the thermal wind balance, and hence the ageostrophic flow must serve to restore that balance. Two stark inferences are that (1) maintenance of the primary flow's geostrophy necessitates the existence of the secondary ageostrophic flow; and (2) the ageostrophic component is determined by, and slaved to, the geostrophic component. In effect, the diagnostic omega equation (eqn [19]) prescribes the ageostrophic component of the flow that must prevail for a specified geostrophic field.

In summary, the foregoing considerations indicate that (1) the geostrophic flow is independent of the ageostrophic flow; and (2) the ageostrophic flow is enslaved to the geostrophic flow. The ramifications of these two deductions are explored in the next two sub-sections.

Evolution of the Geostrophic Flow

The essence of QG flow dynamics is encapsulated by eqns [16–18]. This set of equations forms the basis for the QG version of the so-called Potential Vorticity (PV) perspective. This PV perspective of synoptic and larger-scale flow is physically insightful and cartographically attractive.

Dynamics

Equation [16] states that $\{q + \beta \gamma\}$ is conserved as it is advected with the horizontal geostrophic flow in the absence of diabatic heating ($H = 0$). The physics of this conservation is subtle and simple. The subtlety results from a compensating effect that influences both the rate of change of the vorticity (ζ_G) and a measure (Π) of the stratification, with Π defined such that $q = (\zeta_G + \Pi)$.

It can be shown from eqns [13–15] that

$$D_G \zeta_G / Dt = -\beta v_G - f_0 (\nabla_H \cdot \mathbf{V}_{AG}) \quad [22]$$

$$D_G \Pi / Dt = f_0 \mathcal{L}\{H/N^2\} + f_0 (\nabla_H \cdot \mathbf{V}_{AG}) \quad [23]$$

where $\Pi = f_0 \mathcal{L}\{(1/N^2)g\theta^*/\Theta\}$

Thus, the evolution of both ζ_G and Π is influenced by the ageostrophic horizontal divergence (the term involving $\nabla_H \cdot \mathbf{V}_{AG}$) and the accompanying vertical contraction. For example, horizontal convergence (and thus vertical stretching)

spins up the fluid and thereby increases ζ_G (see eqn [22]) while concomitantly reducing the vertical gradient of θ^* and thereby the stratification measure Π (see eqn [23]). However, the net contribution of this ageostrophic effect upon the development of q is zero.

The ramification for the physics is that the entire flow evolution is condensed to two conservation relationships: pseudo air parcels moving adiabatically with the geostrophic flow in the interior conserve their value of $\{q + \beta \gamma\}$ (eqn [16]), and pseudo air parcels moving adiabatically with the geostrophic flow along the bottom boundary conserve their value of θ^* (eqn [18]).

Thus, the flow evolution, although intrinsically nonlinear, results directly from the prevailing geostrophic flow field modifying, via geostrophic advection, the spatial distribution of q in the interior and θ^* at the surface. Indeed, the instantaneous development can be qualitatively inferred from inspection of the relative configuration of the prevailing QG potential vorticity, q , and the geostrophic flow field itself.

In addition, it can be shown that a localized positive (negative) anomaly of q in the interior is associated with enhanced (reduced) values of vorticity and reduced (enhanced) pressure, and that these signatures decay with distance from the anomaly. Also, the stratification is increased in the vicinity of the anomaly and reduced both above and below. Similar signatures are associated with warm (cold) anomalies of θ^* on the bottom boundary. These features are illustrated schematically in Figure 3.

Flow development and cartography

The ramifications for charting the flow development emerge from recognizing that

- the geostrophic flow field can be viewed as the net of two components, $\psi = \psi_I + \psi_B$, associated respectively with q in the interior and θ^* at the bottom boundary; and
- the interior q and the boundary θ^* fields can each be decomposed into, say, n arbitrary subelements (e.g., q_i and θ_i^*), such that

$$q = \sum_{i=1,n} (q_i), \text{ and } \theta^* = \sum_{i=1,n} (\theta_i^*) \quad [24]$$

It follows, from the linearity of eqn [17], that (ψ_I, ψ_B) satisfy the following relationships:

$$\nabla_H^2 \psi_I + f_0^2 \mathcal{L}\{(1/N^2)\partial \psi_I/\partial z\} = q$$

with $f_0 \partial \psi_I/\partial z = 0$ on $z = 0$

and

$$\nabla_H^2 \psi_B + f_0^2 \mathcal{L}\{(1/N^2)\partial \psi_B/\partial z\} = 0$$

with $f_0 \partial \psi_B/\partial z = (g\theta^*/\Theta)$ on $z = 0$

Analogous relationships also apply for each q and θ^* subelement.

For the cartography of the flow, the foregoing multiple decomposition is particularly apt provided the synoptic-scale flow does resemble numerous distinctive interior q and surface θ^* substructures. In this circumstance, an appropriate and insightful depiction of the flow would be to map the various subelements, and then the flow evolution could be viewed as the interaction between these subelements plus their intrinsic self-development.

Figure 3 A schematic of the flow and thermal pattern associated with a localized positive anomaly of quasigeostrophic potential vorticity (left panel) and a local positive surface thermal anomaly (right panel). The arrows indicate the circumferential flow around the anomalies, with the strength and scale indicated, respectively, by the thickness and lateral extent of the arrows. The dashed lines represent the isentropes.

An illustration

One paradigm for cyclogenesis is the approach aloft of a major trough toward and over a strong low-level baroclinic zone. A schematic illustration of this paradigm when viewed from the QG PV perspective is shown in Figure 4.

At the initial instance (Figure 4(a)), an isolated positive upper-level q -anomaly aloft approaches a low-level baroclinic zone that is aligned east–west. The velocity signature of the upper-level anomaly at the surface serves to distort the baroclinic zone into a wave shape, creating positive and negative anomalies in the surface thermal pattern (Figure 4(b)). Thereafter (Figure 4(c)), the upper-level anomaly's continued distortion of the wave increases the amplitude of the surface thermal anomalies, and in addition the far-field signature of these surface anomalies at upper levels can advect the q -anomaly overhead of the evolving surface front. The latter movement enhances both the strength of the interlevel interaction and the amplitude of the incipient frontal cyclone.

Diagnosis of the Ageostrophic Flow

The interpretive challenge

For simplicity, we consider here, and in the remainder of this section, that the flow is on an f -plane ($\beta = 0$), and is adiabatic and incompressible. In this limit, the omega equation (eqn [19]) reduces to the simpler form:

$$N^2 \nabla_H^2 w + f_o^2 \partial^2 w / \partial z^2 = F \quad [25a]$$

or, more succinctly,

$$\mathcal{M}^2 w = F \quad [25b]$$

where $\mathcal{M}^2$ is the corresponding three-dimensional elliptic operator, and F is, as noted earlier in this article, a known function of the geostrophic stream function.

The numerical solution of eqn [19] for a specified F distribution would yield the full three-dimensional distribution of the vertical velocity field (w) forced by the prevailing geostrophic flow. Here, the focus is on using the omega equation directly to qualitatively infer from inspection of synoptic charts the regions that are favorable for ascent and descent.

The procedure adopted to address this interpretative challenge is to first recognize that

$$(\mathcal{M}^2 w) \alpha - (w)$$

so that a localized region of large negative ' F forcing' favors ascent. Then, to diagnose regions of major ascent and descent, the locations of regions of large (negative or positive) F remain to be inferred from inspection of synoptic charts.

The F forcing

The expression for F can be, and has been, cast in markedly different yet mathematically equivalent forms. Consider the following four formulations.

The conventional formulation:

$$F = f_o \partial [(\mathbf{V}_G \cdot \nabla_H) \zeta_G] / \partial z - \nabla_H^2 [(\mathbf{V}_G \cdot \nabla_H) b] \quad [26a]$$

Refined-Sutcliffe formulation:

$$F = 2f_o \{ [(\partial \mathbf{V}_G / \partial z) \cdot \nabla_H] \zeta_G - D^2 (\partial \lambda / \partial z) \} \quad [26b]$$

'Q vector' formulation:

$$F = 2(\nabla_H \cdot \mathbf{Q}) \quad [26c]$$

'PV perspective' formulation:

$$F = f_o \partial [(\mathbf{V}_G \cdot \nabla_H) q] / \partial z - \mathcal{M}^2 \{ (\mathbf{V}_G \cdot \nabla_H) b \} / N^2 \quad [26d]$$

Here, D^2 is the total deformation and λ the angle of the deformation field's dilatation axis, and $\mathbf{Q}$ is a horizontal vector that for interpretative purposes can be written in the following form:

$$\mathbf{Q} = -|\nabla_H \theta^*| \{ \mathbf{k} \wedge \partial \mathbf{V}_G / \partial s \}$$

where s is a local coordinate aligned along an isentrope such that cold air is located to its left.

Versions [26a] and [26b] arise from direct manipulation of the vorticity and thermal eqns [22] and [23], the $\mathbf{Q}$ vector version from manipulation of eqns [20] and [21], and the PV version from operating directly on eqns [15] and [16]. The relative merit of these formulations depends in part upon their mathematical uniqueness, their potential ability to provide physical insight, and the ease of their usage to diagnose vertical motion.

Figure 4 A schematic illustrating the nature, location, and movement of salient PV features associated with one paradigm for cyclogenesis. A positive PV anomaly at the upper level (red feature) is depicted approaching and interacting with a surface front initially aligned east–west. The flow associated with the PV anomaly is shown as a filled arrow aloft and an unfilled arrow at the surface, and the dashed arrows indicate the flow associated with the evolving surface warm (+) and cold (–) thermal anomalies.

Versions [26a] and [26d] suffer from similar defects: (1) they are not Galilean invariant because, for each version, the relative contributions of their two forcing terms differ in the presence of an additional uniform translational velocity; and (2) for each version, the two terms of the forcing contain equal and opposite contributions. Both these defects militate against attaching a separate physical significance to the two terms. Notwithstanding, version [26d] does provide an elegant interpretation and linkage of the forcing to the PV perspective, and it has been used to shed light on the distinction between mere pattern translation versus flow development.

The remaining two schemes, the refined-Sutcliffe formulation and the $\mathbf{Q}$ vector formulation (eqn [26b] and [26c]), are Galilean invariant and are not subject to the aforementioned cancellation effect. Also, they can be interpreted physically in terms, respectively, of offsetting vortex stretching by thermal adjustment and of maintaining the thermal wind balance. Also, in terms of practical utility, these schemes have been deployed to assess the forcing at a given level using a chart displaying the geopotential and thermal patterns at that level. The next subsection illustrates the application of these two schemes to infer regions of major ascent and descent.

Illustrations

Consider again the paradigm introduced earlier (see Section An Illustration) of cyclogenesis following the approach aloft of a major trough toward and over a surface baroclinic zone. Figure 5 illustrates schematically the nature of the F forcing for, respectively, the refined-Sutcliffe and the $\mathbf{Q}$ vector formulations on a level in the lower troposphere (e.g., 700 hPa) where the vertical velocity field is expected to be significant.

For the refined Sutcliffe formulation, it has been customary to neglect the second of the two forcing terms, and then to qualitatively assess the forcing due to the remaining term:

$$[(\partial \mathbf{V}_G / \partial z) \cdot \nabla_H] \zeta_G$$

This term (the Sutcliffe development term) is proportional to the product of the strength of the thermal wind (the in situ baroclinicity) and the variation of the vorticity along the thermal wind. Hence, for the specified flow setting (Figure 5(a)), the vorticity along the baroclinic zone increases ahead of the trough and decreases behind it, and this in turn demarks the major descent and ascent regions.

For the $\mathbf{Q}$ vector formulation, the method is to exploit the divergence form, $(\nabla_H \cdot \mathbf{Q})$, of the forcing by noting that (1)

Figure 5 A schematic of the forcing term for the omega equation as represented by the Sutcliffe (upper panel) and the $\mathbf{Q}$ vector (lower panel) formulations of the F forcing. The dotted colored lines represent the isentropes of a strong baroclinic zone on the 700 hPa level, the gray continuous lines represent the geopotential height field of a trough, and L is the location of a surface Low. For the Sutcliffe formulation, consideration of the vorticity change along the thermal wind line A^*B^* shows first an increase and then a decrease. For the $\mathbf{Q}$ vector formulation, consideration of the vector wind change along the same line shows a change at the base of the trough indicated by the dotted arrow, and hence a $\mathbf{Q}$ vector (yellow arrow) pointing along the thermal wind.

a region of maximum Q convergence (i.e., negative $\nabla_H \cdot \mathbf{Q}$) favors ascent; and (2) in the vicinity of such a region, the Q vector will tend to point toward the region of convergence and away from a divergent region. The formula for the Q vector

$$\mathbf{Q} = -|\nabla_H \theta^*| \{ \mathbf{k} \wedge \partial \mathbf{V}_G / \partial s \}$$

indicates that it will be large in a region characterized by both strong baroclinicity and a marked change in the strength and/or direction of $\mathbf{V}_G$ along the accompanying isentrope. In effect, the Q vector will be aligned 90° to the right (in the Northern Hemisphere) of the vector wind change.

For the specified flow setting, the largest change of the vector wind along the baroclinic zone is around the base of the trough and is indicated by the dotted arrow in [Figure 5\(b\)](#). Hence, the resulting Q vector (yellow arrow) points down the thermal wind, signifying ascent and descent (respectively) in the regions ahead of and behind the vector. In effect, both formulations agree on the pattern of the vertical motion.

Another diagnostic follows from noting that a causal chain links ascent to cyclogenesis. Ascent in the lower troposphere connotes flow convergence ([eqn \[2\]](#)), and hence vorticity enhancement of an air-parcel advecting downstream with the geostrophic wind ([eqn \[22\]](#)). Further, that enhancement is accompanied by a concomitant decrease in the ambient pressure ([eqn \[7\]](#)), and thereby a tendency for cyclogenesis downstream of the prevailing region of ascent. Likewise, descent is linked to anticyclogenesis. On this basis, the pattern inferred for the vertical motion in [Figure 5](#) would imply that the pre-existing incipient low-pressure system would move along the thermal wind (the so-called steering effect).

Cursory Case Study

Here, the appropriateness and the utility of the QG PV perspective and the interpretative diagnostic schemes discussed in Section Physical Interpretation are examined for one particular realized event of cyclogenesis. The event occurred over the Atlantic from 31 December 2006 to 1 January 2007. The synoptic setting at 12 UTC on 31 December 2006 was discussed in Section Mathematical Formulation and is shown in [Figures 1](#) and [2](#).

The PV Perspective

[Figure 6](#) shows the flow field and a proxy for the net QG PV (i.e., $q + \beta y$) on the near-tropopause 315 K isentropic surface (upper panels), and the geopotential and potential temperature fields on the 1000 hPa surface (lower panels). The displays are for 12 UTC 31 December and 00 UTC 1 January.

At the upper level, the initial potential vorticity distribution has a narrow and elongated band of sharp q gradient aligned along the tropopause-level jet with an accompanying short-wavelength equatorward protrusion of the jet at 60° W. The latter constitutes a positive q anomaly, and in the subsequent 12 h this feature is seen to dilate and extend further south-eastward to form a strong and distinctive filament.

At the surface, a band of strong baroclinicity extends eastward from the Carolinas at 12 UTC. An incipient Low is located

on this band beneath the southeastern extremity of the PV protrusion aloft. In the subsequent 12 h, the surface pattern exhibits a classical development with the thermal field undergoing a strong distortion to form a cold and warm frontal palette separated by a warm sector. The attendant Low develops rapidly, and its eastward movement shadows that of the q anomaly aloft.

This development resembles the cyclogenesis paradigm introduced in Section Cursory Case Study. [Figure 6](#) lends credence to the assertion that the atmosphere has distinctive PV subelements, pinpoints clearly the subelements involved in the development, and illustrates and confirms that insightful qualitative inferences can be drawn regarding the interaction between the subelements and the subsequent short-term movement of the anomalies.

Q Vector Diagnosis

[Figure 7](#) is the counterpart of [Figure 6](#), but now the displayed fields are for the 700 hPa surface and show the potential temperature and wind field (upper panels) and the Q vector pattern and vertical motion (lower panels).

The patterns in the upper panels allow one to quickly and qualitatively infer the location of large Q vector contributions. At the earlier time, there is a significant flow change up- and downstream of the cusp in the thermal pattern near (39° N, 55° W), and this is consistent with strong eastward-pointing Q vectors in this region. At the later time, both the new location of the cusp and the warm frontal zone coincide with strong flow changes with dominant Q vectors aligned, respectively, north-eastward and southeastward.

In the lower panels, the quantitatively computed Q vectors confirm the foregoing qualitative inferences, but their pattern also indicates that the F forcing has a more spatially refined substructure that is itself confirmed by the displayed pattern of the vertical velocity field.

Furthermore, note that at the earlier time ([Figure 7\(c\)](#)), the Q vector pattern is indicative of ascent in the neighborhood of the surface Low and along the contiguous cold and warm fronts. This signature, taken in conjunction with the south-westerly geostrophic flow above the Low at 700 hPa ([Figure 7\(a\)](#)), correctly foreshadows the subsequent movement of the Low to the northeast (cf. [Figure 6\(c\)](#) and [6\(d\)](#)). At the later time, the Q vector pattern ([Figure 7\(b\)](#)) has a similar overall structure but is stronger and more coherent. Again, consistent with this signature and the 700 hPa flow above the surface Low, the latter moves northeastward and continues to develop rapidly (not shown).

The foregoing results underline the practical utility of the omega equation for indicating qualitatively and readily the regions of major ascent, and concomitantly pointing to the regions favorable for cyclogenesis.

Limitations and Refinements

The QG set of equations provides a first-order and remarkably insightful representation of synoptic and larger-scale atmospheric flow. The emphasis here has been to understand the fundamental dynamics of QG flow and then to

Figure 6 Charts for 12 UTC 31 December 2006 (left panels) and 00 UTC 1 January 2007 (right panels). Panels (a) and (b) display the flow field and the natural logarithm of PV, i.e., $\ln PV$ (a proxy for the quasigeostrophic PV) on the 315 K isentropic surface. Panels (c) and (d) display the height field (blue contours every 50 m) and potential temperature distribution on the 1000 hPa surface for the corresponding times.

Figure 7 Panels A and B show the flow field and potential temperature pattern on the 700 hPa surface at, respectively, 12 UTC 31 December 2006 and 00 UTC 1 January 2007. Panels C and D display both the vertical motion field (negative values indicate rising motion) and the $\mathbf{Q}$ vectors on the 700 hPa surface for the corresponding times. Note that here the $\mathbf{Q}$ vectors have been computed with the full horizontal wind rather than the geostrophic wind.

illustrate its utility for understanding day-to-day weather development. However, the range of application of the QG set is much broader. For example, the set provides the platform for the theoretical study of large-scale planetary (Rossby) waves and their propagation, barotropic and baroclinic instability, the perturbing effect of orography upon the large-scale flow, and the large-scale dynamics of the stratosphere.

Nevertheless, QG is only a first-order representation of synoptic-scale flow, and it is not strictly valid in flow regimes with strong ageostrophic flow such as usually prevails for large-scale tropical convective systems, in the finer-scale features of extratropical weather systems, and in the vicinity of major mountain ranges. Also intrinsic to the QG representation is the exclusion of buoyancy and acoustic-wave phenomena.

Extensions of QG theory have been developed that are predicated upon the existence of some higher form of dynamical balance beyond that of geostrophy (e.g., the semi-geostrophic and geostrophic momentum set of equations).

Introduction

Large-scale undulations in the westerly winds are related to an ideal form of motion known as the ‘Rossby’ or ‘planetary’ wave. These waves owe their existence to the rotation and spherical shape of the Earth. Weather patterns and the general circulation are mostly much wider than the depth of the atmosphere: viewed from the side, a weather system is 100 to 1000 times thinner (vertically) than its width. This extreme thinness, beyond reminding us of the fragile nature of the atmosphere, causes horizontal winds to be stronger than vertical winds in such weather systems. Stable layering of the air, with its great variations in density, reinforce this inequality. Waves then become possible, which are dominated by nearly horizontal wind patterns, in many ways unlike the familiar waves on the sea or those of sound or light.

In their most general form, Rossby waves have an important bearing on what we call ‘weather’ and on the form of the general circulation of the Earth’s atmosphere and its oceans, and on the atmospheres of other planets. Indeed, the form of the general circulation is in part shaped by Rossby waves. In their most general form, Rossby waves occur widely in fluid flows of many kinds (e.g., in hurricanes). To understand these waves completely requires a challenging amount of mathematics and physics, but many of their properties can nevertheless be appreciated through ideas, observations, and experiments that could be found in a high-school physics course. Because the language of science can be artificially complex, we provide translations of some unfamiliar terms inside brackets {}. Some mathematical equations are included, but these can be skipped by those unfamiliar with them.

Horizontal Propagation

If a westerly wind {one that blows eastward} passes over a mountain range, undulations develop downstream, meandering north and south with regularity. This is somewhat like a brook flowing rapidly over a stony bottom, where small ripples and longer gravity waves are seen on the surface. The uneven bed of the fluid disturbs the flow, sending out waves. Waves trying to ‘stem the current’ and propagate upstream are particularly strong: these waves are held fixed in space. They ‘resonate’ with the rocks and build up in amplitude (yet, more subtly, their energy does propagate away from the stony source, upstream for ripples and downstream for gravity waves). Such a pattern, calculated for the much larger-scale flow appropriate to Rossby waves, is seen in Figure 1. The waves here are excited by flow of a single layer of fluid over an isolated mountain; the ‘mountain’ is idealized in the form of a circular cylinder of finite height. For a westerly wind speed of 30 m s^{-1} , at latitude 40° on the Earth, the wavelength {the distance from one northward undulation to the next} is about 8200 km. Rossby

waves are primarily horizontal motion, rather than vertical. Unlike waves at the surface of the sea, but somewhat like longer gravity waves on a stream, they involve the entire fluid, and help to shape its circulation. If the mean winds were reversed in Figure 1, they would flow over the mountain with very little disturbance: Rossby waves cannot then be generated.

In large-scale atmospheric flow, isobars {lines along which pressure is constant} nearly coincide with streamlines {lines along which the wind is directed}; this is why useful weather maps show the atmospheric pressure. Notice at once that the meandering flow in Figure 1 has a cyclonic low-pressure center just downstream of the mountain, with relatively high pressure upstream. This indicates that the wind is pressing eastward on the mountainous solid Earth, and in response the Earth is pressing westward on the atmosphere {with a horizontal force found by adding up everywhere the pressure multiplied by the slope of the topography}. It seems that in generating a Rossby wave, the mountain is also exerting, over time, a westward force on the atmosphere. In fact, this ‘wave-drag’ is a key part of the angular momentum balance of the atmospheric circulation. With the passing of the seasons, fluctuations in this balance cause the speed of rotation of the Earth to fluctuate, and the length of the day to change by about 1.5 ms.

The observed northern hemisphere flow in the upper troposphere is shown as an average over the winter season (Figure 2a). The deviation from circular streamlines, which would correspond to strictly east–west winds, is the ‘stationary’ or ‘standing’ wave field of the atmospheric general circulation (see *Dynamical Meteorology: Stationary Waves (Orographic and Thermally Forced)*). The flow is westerly throughout most of the region, which does not extend south into the trade winds. Where the streamlines squeeze close together the winds

Figure 1 Rossby waves in westerly flow over an idealized mountain (a circular cylinder). From McCartney M, *Journal of Fluid Mechanics*, 68: 71–95, 1975. Shown are the streamlines, stationary pattern along which the wind is directed.

Figure 2 (a) Streamlines (solid) and absolute vorticity, $\xi + f$, averaged at the 300 hPa level in the upper troposphere. Figure from Lau NC, *Journal of the Atmospheric Sciences*, 36: 996–1016, 1979. The deviation of the streamlines from circles is a wave pattern analogous to Figure 1. If this were simply barotropic Rossby waves, the dashed and full lines would coincide. Continents are shown with dotted curves; North America is at the bottom of the figure. (b) Cross sections of the geopotential height of the atmosphere at 601° N (a), 451° N (b), and 251° N (c). This is the flow averaged in time during the winter season. Here the vertical axis is pressure-level and the horizontal axis is longitude. To a good approximation this can be viewed as a plot of pressure with respect to actual altitude and longitude. Figure from Lau NC, *Journal of the Atmospheric Sciences*, 36: 996–1016, 1979. The flow in (a) cuts through this figure at the 3000 hPa level.

are stronger: this occurs downwind of the Himalayan plateau at the western side of the Pacific Ocean, and downwind of the Rocky Mountains, at the western side of the Atlantic Ocean. Of course at any given moment the winds will not look like this figure, for transient waves and eddies, some of them associated with the jet stream, are as strong as the mean winds. Between two and three waves fill a latitude circle, in this pattern.

Vertical Propagation

Complementing this purely horizontal view of the circulation, a vertical cross section of the atmosphere, running east and west, shows that in a broad-brush sense the wind patterns vary very little with altitude, though they grow in strength as one moves up to the top of the troposphere (where the jet streams are strongest). This means that a ‘barotropic’ model, {such as one with a single layer of uniform-density fluid, as in Figure 1}, should have some validity. Notice, as in the horizontal map of the same wind field (Figure 2(a)), and the theoretical calculation behind Figure 1, that major low-pressure regions lie in the lee of the Himalayan Plateau in Asia, near 90° E and in the lee of the Rocky Mountains of North America at 90° W longitude. Because a geostrophic {large-scale} wind moves with high pressure to its right (in the Northern Hemisphere, conversely in the Southern Hemisphere), there are northerly winds in the lee of the mountain ranges, as in Figure 1.

A more subtle feature, however, shows that the winds and temperature are organized in a pattern that tilts to the west as one moves upward through the atmosphere (Figure 2(b)). This tilt is a signature of several important things. It signifies upward propagation of energy and of easterly momentum. The easterly {westward} pressure force exerted by the solid Earth is transmitted upward through the atmosphere by ‘wavy’ layers of air that exert pressure forces similar to those on the solid mountain slopes. These forces alter the winds aloft. Upward propagation of a given amount of energy into regions of thinner (less dense) atmosphere leads to increasing velocity with height (because the kinetic energy is the product of air density and squared velocity). For this reason, Rossby waves that reach the stratosphere can be accompanied by strong winds, and can drive strong changes in the mean westerly winds.

The tilted pattern also indicates that north–south wind velocities, v , and temperature, T , have a systematic correlation. Their product, vT , is the poleward {toward the North or South Pole depending on which hemisphere one is in} transport of heat. Recall (see **Radiation Transfer in the Atmosphere: Radiation, Solar**) that most of the significant motions of the atmosphere and ocean are driven by solar radiation, heating the tropics, with the heat radiating back to space most strongly near the poles. Rossby waves, or motions with some of their properties, contribute to the north–south ‘heat pipe’ in this giant heat engine. This discussion fills out the fully three-dimensional picture of the two-dimensional problem shown in Figure 1.

Because Rossby waves exist throughout the depth of the atmosphere, they are not ‘superficial oscillations,’ but rather an expression of forces acting on the entire circulation. An isolated cyclone, if it is large enough in size and weak enough in wind velocity, will ‘burst apart’ into Rossby waves, forming new,

Figure 3 The breakup of an initial weak vortex (a). Shown are streamlines or constant-pressure curves. The ‘banana’ shaped patterns are high-pressure and low-pressure cells associated with Rossby waves. This is a single layer of fluid without a mean westerly wind, using a β -plane approximation to the rotating Earth. This numerical solution is periodic east and west, with waves entering the domain from the east after exiting in the west. From Rhines PB, *The dynamics of unsteady currents*. In ED Galdberg (ed.), *The Sea*, Vol. VI, pp. 189–318, New York: Wiley, 1977.

elongated cyclones and anticyclones that gradually fill the fluid with motion (Figure 3). In this experiment, the fluid itself oscillates gently, moving only slightly compared with the movement of the wind patterns. In the figure we have no mean westerly wind, so that most of the fluid is motionless. Stronger, more realistic cyclones do not radiate waves so efficiently, but the forces involved in the waves are still at work, for example, nudging hurricanes out of the tropics toward the poles.

Examples: Blocking Patterns in the South-East Pacific and Teleconnections over North America

Observations of winds at the 300 hPa level in the Pacific (Figure 4) show a structure that illustrates the nature of Rossby wave propagation. Cumulus convection in the western tropical Pacific provides a large-scale pattern of divergent winds aloft. A train of cyclones and anticyclones appears south of Australia and veers south-eastward toward Chile, where it creates a lasting circulation cell strong enough to be called a ‘blocking’ pattern. The figure shows correlations of the winds with a time-series that expresses this blocking: the winds themselves form a similar pattern. The waves arrive quickly (the speed of individual cyclones and anticyclones being about 5° of longitude per day, which appears to be slower than the south-eastward development of the pattern as a whole). They decay slowly, influencing a vast region of the South Pacific and reaching into the South Atlantic. In a simpler fluid than the atmosphere, convection in the tropics would stimulate a more local response: here, waves cause a ‘teleconnection’ round half of the circumference of the Earth.

When the close-in views of theoretically solved Rossby waves (Figures 1 and 3) are expanded to the whole sphere, the waves tend to propagate along great-circle paths. While theory predicts their structure in the simplest circumstances, computer models, which solve the mathematical equations approximately, must be employed if realistic mean wind patterns and land topography are included. The modeled Rossby-wave field generated by a similar pattern of equatorial heating by the ocean, Figure 5, has two branches propagating south-eastward and north-eastward from the western Pacific. The wave train crossing North America is similar to the ‘PNA pattern’ that is

associated with ENSO events (more will be said about this pattern below).

Some Specific, and Rather Technical, Results

What features of the atmosphere are explained in some way by Rossby waves? Begun a century ago as an exploration of weak oscillations of the atmosphere and oceans (e.g., the tides raised by Moon and Sun), the theory of Rossby waves now provides insight into the very heart of atmospheric (and oceanic) circulation dynamics. These waves are related to the meandering north and south of the westerly winds and, less directly, to the synoptic eddies that shape our weather. Rossby waves contribute to understanding the global pattern of these westerly winds, the enhancement of cyclonic disturbances in the lee of major mountain chains, the location and shape of storm tracks in the western Atlantic and western Pacific, some forms of blocking and stagnation of air masses, the propagation of energy in long waves upward to the stratosphere, the transport of east–west momentum with these waves, and the attendant deceleration and ‘sudden warming’ of the wintertime vortex that sits above the North Pole.

Along the Equator, oceanic heat and water vapor drive cumulus towers that heat the larger-scale atmosphere. The winds converge below and diverge above such a heat source, and air pulled into the pattern creates a pattern of circulation extending both east and west from the heat source. Rossby waves propagating westward from the region of forcing control the shape of this pattern to the west, while Kelvin waves describe the movement east of the heating. At a yet larger scale, the atmosphere signals the onset of El Niño in the tropical Pacific by sending a train of waves across North America: in the simplest idealization these are Rossby waves (meanwhile, in the sea below, Rossby waves move westward along the Equator to reinforce the recurrence of El Niño). In the lower troposphere in summer great anticyclones fill the North Atlantic and Pacific Oceans, and these are established by monsoon forcing (warming of the land surface) yet organized and shaped by westward propagation of low-frequency Rossby waves. More distant relatives of the Rossby wave account for the basic instability of the primary, east–west

Figure 4 A map showing the correlation between the north-south winds at 300 hPa level with the time series of south-east Pacific blocking. The panel labeled D-4 represents the correlation pattern 4 days before maximum blocking, and the sequence proceeds in time to

Figure 5 Computer models of the atmospheric circulation play a key role, not just in weather forecasting, but in developing ideas and testing theories of the underlying dynamics. Here, trains of Rossby waves propagate in both hemispheres from a source of cumulus-convective heating in the western equatorial Pacific. The model takes the observed, fully three-dimensional structure of the circulation and calculates the change in the winds arising from tropical heating by the warm ocean. The waves all emanate from the western equatorial Pacific, moving eastward along (very approximately) great-circle paths. Plotted contours show the north-south wind (not including that of the time-averaged winds) in the upper troposphere; contour interval 0.5 meters per second. From Jin F and Hoskins BJ, *Journal of the Atmospheric Sciences*, 52: 307-319, 1995.

atmospheric circulation: baroclinic instabilities, which are the model of cyclonic storm development, tapping the potential energy of the atmosphere, and barotropic instabilities, which tap the kinetic energy of the mean atmospheric flow. In the stratosphere, very large-scale Rossby waves describe the undulations of the vortex sitting over the winter pole. They are excited by upward propagation of Rossby wave energy from the intense winter circulation below. The restoring force that gives us Rossby waves also inhibits mixing of fluid north and south, and in this way makes possible the ozone hole.

Before being completely carried away by the potency of this idea, however, we have to warn that Rossby waves are in competition with other forms of flow, particularly with turbulent, large-amplitude winds that are not waves at all. At the scale of the larger weather systems, the 'flow' dynamics and the 'wave' dynamics are nearly equal in importance.

Basic Principles

The conservation principle for potential vorticity (*see Dynamical Meteorology: Potential Vorticity*) helps to simplify the notion of Rossby waves, and also unifies them with the 'flow' dynamics just mentioned. Potential vorticity (PV) combines the dynamical effects of the spin of the Earth about its axis with the much smaller-scale spin of elements

4 days after peak blocking. The apparent wave train propagates from Australia south-eastward across the Pacific. 'Blocking' here means a period of at least 5 days when the 500 hPa pressure is at least 0.5 standard deviation above the norm. The source of the wave train is thought to be the cumulus convection in the western equatorial zone, and hence there is a strong correlation of warm El Niño periods with blocking patterns at higher latitude (SOI index-blocking index correlation reaches -0.8 during the past 15 years). From Renwick JA and Revell MJ, *Monthly Weather Review*, 127: 2233-2247, 1999.

of the fluid about their centers. The spin of the Earth is, in effect inherited by the fluid atmosphere, and concentrated into small, spinning storms. PV also incorporates effects of the sloping isentropic surfaces, and the shape of the atmosphere's lower boundary. PV is thus a combination of small-scale fluid properties and large-scale environmental properties. Using the time derivative following the motion of the fluid (and with PV denoted by q), eqn [1] describes conservation of q following an ideal fluid element as it moves.

$$\frac{Dq}{Dt} = 0 \text{ where } q = \frac{f + \zeta}{h} \quad [1]$$

We have neglected friction, heat sources, and the effects of small, unobserved, turbulence here. PV is related to, yet more general than, the conservation of angular momentum encountered in the physics of spinning bodies. Here f is known as the Coriolis frequency. It is equal to twice the vertical component of the Earth's rotation vector (eqn [2], where Ω is the Earth's rotation rate (in radians per second) and ϕ is the latitude).

$$f = 2\Omega \sin \phi \quad [2]$$

Rather like a Foucault pendulum, the horizontal flow of the atmosphere picks out the vertical component of the rotation vector. ζ is known as relative vorticity (also resolving just the vertical component), which is twice the average rate of spin of small fluid elements about their centers; finally, h is the thickness of the layer of fluid, measured along the local vertical. As the fluid moves, it may trade off its small-scale spin (ζ) for its large-scale 'planetary spin' (f) by moving north or south: this is the essence of the Rossby wave. The thickness h may also be involved in the trade-off, helping or hindering it. A key quantity suggested by this description is the rate of change of the planetary spin, f , with latitude. This is known as β , defined as in eqn [3],

$$\beta = \frac{2\Omega \cos(\text{latitude})}{a} \quad [3]$$

where a is the Earth's radius, 6380 km (± 3 km). In SI units (meters $\times$ seconds) $^{-1}$, $\beta = 2.28 \times 10^{-11}$ multiplied by the cosine of the latitude. The 'beta-effect' is the name given this systematic gradient {variation} of PV provided by the spherical shape of the planet.

For a single layer of homogeneous fluid like ordinary water, h is the full depth of the layer: in this case we can have 'topographic Rossby waves' due to a slope of the solid bottom (variation of h), instead of the spherical shape of the Earth (variation of f). For a fluid layered with significant density variation (like the ocean or the atmosphere), the conservation of PV can be applied to a small fluid element, with h being the vertical thickness of the density layer. PV thus has a dual nature: it gives a conserved quantity at each point in the fluid and yet it also has a vertically averaged sense of being conserved, for an entire layer of fluid {this known as 'barotropic' PV}. Remarkably, many aspects of atmospheric Rossby waves can be largely understood in terms of the latter, simpler, barotropic PV. A map of PV throughout a fluid can be mathematically 'inverted' to give much of the velocity and density field (though a part of the flow for which PV = 0 is 'invisible' to PV analysis), and a map showing curves of constant PV for the time-averaged state of the atmosphere (with mean winds and mean temperatures) describes the

restoring effect for the waves. Indeed, fluid can flow rather freely along such curves of constant PV (known as 'geostrophic contours' or just mean-PV contours). The persistent variation of f with latitude tells us that east-west winds are favored on a rotating planet, and north-south winds may often lead to waves.

It is exceptionally handy that the fundamental dynamical quantity (PV) for the atmosphere is nearly unchanging, like the concentration of a trace chemical following the circulation of the air. This adds great intuitive resource because we can actually see tracers move, distort and mix, and we can 'see' PV in models and observations behaving in many of the same ways. Rossby waves are the shimmering of the mean PV contours of the atmosphere.

Barotropic Rossby Waves

For the case when the layer thickness, h , is effectively constant, we have $\zeta + f$ as the active part of PV. An ideal situation would be a single layer of incompressible fluid (like water) of constant depth. It happens that this idealization is immensely powerful, providing approximate wave solutions for the more complex environment of the stratified atmosphere.

Carl-Gustav Rossby, working at MIT in 1939, introduced the useful approximation for middle latitudes, known as the 'beta-plane.' It approximates the spherical Earth locally by a plane tangent to it, allowing simpler mathematics using Cartesian coordinates to replace the full spherical coordinates. Far from the tropics, the Coriolis frequency can be approximated as in eqn [4] where γ is the north-south position, measured from some mean latitude γ_0 .

$$f = 2\Omega \sin(\text{latitude}) \approx f_0 + \beta\gamma \quad [4]$$

Rossby Waves in an Atmosphere at Rest

Let us now use these ideas to construct a basic Rossby wave for an atmosphere otherwise at rest (without the usual east-west mean winds). Newton's second law, the conservation of momentum, gives us equations in both horizontal directions, x (eastward) and y (northward), for the corresponding velocity components u and v . If we set up the wave with purely north-south motion, $u = 0$, the momentum equations express an east-west force balance between the pressure gradient and the Coriolis force (known as geostrophic balance; eqn [5]) and a north-south force balance between acceleration per unit mass and pressure gradient (eqn [6])

$$-fv = -\frac{1}{\rho} \frac{\partial p}{\partial x} \quad [5]$$

$$\frac{\partial v}{\partial t} = -\frac{1}{\rho} \frac{\partial p}{\partial y} \quad [6]$$

Eliminating the pressure, p , between these two equations gives a wave equation for v (eqn [7]).

$$\frac{\partial^2 v}{\partial x \partial t} + \beta v = 0 \quad [7]$$

In eqn [7], where $\beta = \partial f / \partial y$, approximated as a constant in the equation. Assuming a wave of the form $v = A \cos(kx - \omega t)$, we substitute into the wave equation to find eqn [8].

$$\omega = -\frac{\beta}{k} \quad [8]$$

This key relation between the wavenumber k {which is 2π divided by the wavelength} and the frequency ω tells us that longer waves have higher frequency, and their propagation speed, c (the phase speed) is westward, with magnitude β/k^2 . In more familiar wave systems, for example, nondispersive sound waves, light waves, or waves on a vibrating string, the frequency varies directly with wavenumber and the propagation speed c is a constant. The character of dispersive waves is that a localized disturbance breaks into sine-wave components of gradually varying length (as with a pebble thrown into a pond). By contrast, nondispersive waves like sound and radio waves preserve the properties of isolated pulses, making possible communication to a great distance.

The Restoring Force for Rossby Waves

The force balance above shows that the pressure gradient is the restoring force for the waves, and that this north–south gradient arises indirectly from the east–west force balance. Large-scale winds, slowly varying in time (relative to a day) are nearly geostrophic (see **Dynamical Meteorology: Quasigeostrophic Theory**), with pressure gradient balancing the horizontal Coriolis force (which is at right angles to the wind). Because the Coriolis frequency and hence the Coriolis force on the air parcels increase with latitude, so too do the north–south pressure variations, and these provide the needed restoring force, driving the acceleration of the wind.

The principle of conservation of PV gives a clearer description of the workings of the Rossby wave. An air mass that moves northward in a standing wave pattern, conserving the sum $\zeta + f$, will have to develop negative spin or vorticity, ζ , as it encounters smaller values of f found at high latitude. This anticyclonic spin matches the northward velocity, west of the parcel, and the southward velocity to its east (Figure 6),

Figure 6 Showing how a parcel of air moved northward in a standing wave, conserving its potential vorticity $\zeta + f$, develops negative (anticyclonic) spin ζ , which affects fluid to the east and west, reinforcing the north–south winds.

enforcing the basic wave pattern. In downwind regions where the wave has not yet penetrated, this spin will extend the pattern downwind at a rate twice the mean westerly wind speed.

When the wave is oriented in an arbitrary direction, it has two wavenumbers or, more succinctly, a wave-vector $\mathbf{k}$ with components k (east–west) and l (north–south). The corresponding equation (for a fluid without mean east–west winds) is now (written in terms of the stream function, ψ) given by eqn [9].

$$\frac{\partial}{\partial t} \nabla^2 \psi + \beta \frac{\partial \psi}{\partial x} = 0 \quad [9]$$

The quantity ψ is a close approximation to the pressure or geopotential height field, as well as giving the horizontal velocities ($u = -\partial \psi / \partial y$, $v = \partial \psi / \partial x$), and $\nabla^2 \psi$ is the horizontal Laplacian, $\partial^2 \psi / \partial x^2 + \partial^2 \psi / \partial y^2$. The equation is a form of conservation of PV, rewritten as $PV = \nabla^2 \psi + \beta y$. The frequency relation, found by substituting a wave of the form $\psi = \exp(ikx + il y - i\omega t)$ in the equation, is now given by eqn [10], where α is the direction of $\mathbf{k}$ with respect to east.

$$\omega = \frac{-\beta k}{k^2 + l^2} = \frac{-\beta \cos \alpha}{|\mathbf{k}|} \quad [10]$$

This relationship is plotted in Figure 7. A key property of dispersive waves is the velocity of energy propagation, known as the group velocity. This vector has magnitude (5) equal to the westward component of phase speed, and it points in a direction 2α . This vector has magnitude (eqn [11])

$$\frac{\beta}{|\mathbf{k}|^2} \quad [11]$$

The group velocity is perpendicular (pointing inward) to the circles of constant frequency in Figure 7. A remarkable

Figure 7 Frequency–wavenumber diagram for Rossby waves in a fluid without mean east–west winds. Here we have wavenumbers k and l in the east and north directions, respectively, as horizontal and vertical axes. Curves of constant frequency, are plotted, with frequency increasing toward the origin. The waves reverse the normal property of nondispersive waves, having higher frequency for longer wavelength. Energy propagation for a given wave is directed perpendicular (and inward) to these curves. Thus, for example, a wavevector pointing from the origin upward/leftward (northwestward) has wave crests and winds directed north–east–south–west, and energy propagation southward.

property of Rossby waves is that their wave crests always move westward relative to the air, with westward speed also given by expression [11], even though their energy can propagate in any direction. If a steadily oscillating force is exerted at a point in the fluid, it will radiate Rossby waves in all directions (Figure 8). The theory gives the solution as a form of Bessel function {known as the Hankel function of the second kind}, multiplied by a westward-traveling sine wave, written explicitly as $\psi = \exp(i\beta x/2\omega - i\omega t)H_0^{(2)}(\beta r/2\omega)$. The wave crests form parabolas on the horizontal plane that sweep westward while collapsing toward the westward part of the x -axis.

Effect of Mean Zonal Winds

An east–west wind, U , Doppler-shifts the waves; if we restrict our interest to standing or stationary waves, we replace time derivatives with x -derivatives, or equivalently replace ω by $-kU$ in the frequency relation. Instead of eqn [10], this gives eqn [12].

$$kU = \frac{k\beta}{k^2 + l^2} \quad [12]$$

And instead of the wave equation [9], we have eqn [13].

$$\nabla^2 \psi + \frac{\beta}{U} \psi = 0 \quad [13]$$

Evidently, a westerly wind generates Rossby waves, all of the same wavelength (eqn [14]).

$$\frac{2\pi}{\sqrt{k^2 + l^2}} = 2\pi \sqrt{\frac{U}{\beta}} \quad [14]$$

We see from this formula that faster winds make longer waves, and in regions of easterly wind ($U < 0$) there are no simple waves at all. The group velocity is found by adding the intrinsic group velocity of the Rossby wave to the mean wind velocity. Using relation [11], the intrinsic group velocity has

Figure 8 Rossby waves generated in a fluid, initially at rest, by an oscillating force where the field has its highest peak. This is a perspective view of the pressure, or streamfunction, seen from the south-west. Short Rossby waves have eastward energy velocity, and hence appear to the east, while long waves with nearly east–west velocity extend west of the forcing. On the plane beneath, the contour plot of the same field shows the parabolic shape of the wave-crests. With time they sweep westward and ‘collapse’ on the latitude line emanating westward from the forcing.

magnitude that just equals U . Taking account of the direction of energy propagation, the waves’ energy propagates with velocity $2U(1 + \cos \theta)$, in a direction θ measured with respect to east. They fill an ever-expanding circle downstream of the source of waves.

In the more general situation of propagating (rather than stationary) waves on a westerly wind, the two above analyses combine to give an east–west wavespeed ω/k which is $U - (\beta/|k|^2)$. This is Carl-Gustav Rossby’s ‘trough formula.’

Forcing and β -Plumes

There is one important signal missing from the above discussion. Waves with crests (and winds) running nearly east and west have $k \ll l$ and have significant energy velocity even though their intrinsic frequency is small. At very low frequency, keeping the wavelength constant, the direction of energy propagation is due westward, and is sufficiently fast to overcome a westerly wind. This produces what can be called ‘ β -plumes,’ which are nearly steady cells of circulation reaching westward from their point of generation. The above expression for the energy velocity, $\beta/|k|^2$, tells us that for north–south length scale L , the circulation plume will propagate westward at speed βL^2 relative to the mean wind. In the case of flow over a mountain range, this plume can reduce the flow upwind of the mountains, expressing a blocking of the wind by the mountain. With a little friction added, the β plume can become a steady, closed circulation. A solution for the streamlines due to a point-source of PV, Figure 9,

Figure 9 The β -plume is a circulation generated by a small region of forcing (e.g., heating of the atmosphere with convective clouds). Here, in the middle latitudes, on a β -plane the circulation reaches west of the forcing forming an elongated gyre of streamlines. Rossby waves of very low frequency are active in setting up this western extension of the circulation. The forcing at the origin could be a small region of heating by cumulus convection (driving divergent flow in the upper troposphere, and hence anticyclonic circulation and convergent winds, with cyclonic circulation in the lower troposphere), or a mechanical ‘twisting’ force concentrated at the origin. This is a plot of the theoretical result, which is a Bessel function with imaginary argument multiplied by an exponential.

complements the oscillating Rossby wave point source in [Figure 8](#). Here the forcing would produce a circular vortex in absence of the β effect (and indeed, near the forcing the streamlines are circular). But Rossby wave propagation makes the vortex lop-sided, extending far to the west.

The beta effect is particularly strong in the tropics and, together with gravity wave and Kelvin wave dynamics, helps to shape circulations there. An idealized steady heat source at the Equator, [Figure 10](#), causes a low-level convergence of the winds, which rise into the heating region. This is for an atmosphere initially at rest. Yet this convergence forms a double cell of circulation west of the heating region, which is again a β -plume. The winds are drawn in from east of the heating in another 'plume' that is shaped by Kelvin wave dynamics (see **Dynamical Meteorology: Kelvin Waves**). Motions that involve strong horizontal temperature variations and corresponding vertical velocity variations (through the thermal-wind balance) are termed baroclinic (see **Dynamical Meteorology: Baroclinic Instability**), whereas winds with little vertical variation in the pattern of the velocity are termed equivalent-barotropic. The winds produced by heating here are quite baroclinic, yet with a significant equivalent-barotropic contribution. When the observed mean atmospheric winds are added to this model, the very different pattern of nearly stationary Rossby waves

Figure 10 On the Equator, the pressure response of an atmosphere without mean winds to heating by cumulus convection (shaded region) involves both Rossby and Kelvin waves. Here the β -plume draws air in from the west to feed the low-level convergence, while drawing in from a 'Kelvin plume' to the east. Panel (a) shows the upper troposphere, where the updrafts diverge outward, and panel (b) shows the lower atmosphere, where convergent winds feed the updraft. Because the sign of f changes across the Equator, we have a double-celled pattern rather than the single circulation cell in [Figure 8](#) (cyclonic wind cells below, anticyclonic above in the β -plume west of the forcing). From Jin F and Hoskins BJ, *Journal of the Atmospheric Sciences*, 52: 307–319, 1995.

appears downwind of the forcing, [Figure 5](#): yet we can still see the β -plume upwind.

Horizontal Propagation: Refraction, Waveguides, and Instability

Rossby waves follow propagation pathways ('rays') in an approximate sense, and these rays are bent by variations in large-scale PV from the time-averaged winds, the thermal structure, and topography of the solid Earth. Preferred paths ('waveguides' or 'ducts') of the waves are created in this way, for example, in the core of the westerly winds, along the Equator, and in the upper polar troposphere.

We have seen some of the topographically induced standing wave patterns of the atmosphere that at least in part are attributable to Rossby wave dynamics. Consider now the kind of perturbation {alteration, often weak or slight} to the mean standing-wave circulation arising from an additional source of waves, as in [Figure 5](#). For example, during El Niño events in the Pacific, the extraordinarily warm sea-surface temperature can excite waves in the atmosphere passing above. Yet it is found that the wave pattern generated is sensitive to the location (east and west) of the forcing region; this would not be the case for a simple Rossby wave problem. We must generalize the restoring effect for Rossby waves to include PV gradients in the mean winds themselves. In eqn [13], β is replaced by $dq/dy = \beta - \partial^2 U / \partial y^2$ for this barotropic model. Now consider what this does. The curvature of the $U(y)$ profile (which is the gradient of relative vorticity) is subtracted from β . For an easterly jet, the $q(y)$ profile now has a 'flat spot' with small PV gradient cut like a plateau in the ' β hillside.' A westerly jet gains a concentrated gradient at the core of the jet. The concentration of vorticity in the mean flow augments the β -effect for the case of the westerly jet: it is the simple sum of the planet-scale PV and the vorticity of the time-averaged winds that counts. The ray paths describing propagation of groups of short Rossby waves will bend toward from regions of large β^* , as defined in eqn [15].

$$\beta^* = \left[\frac{dq/dy}{U} \right]^{1/2} \quad [15]$$

In this way waves will be deflected away from an easterly jet and trapped inside a westerly jet, which thus acts as a waveguide.

Three panels in [Figure 11](#) show the observed mean winter westerly wind, the barotropic PV gradient, dq/dy , and the effective restoring term β^* . Using similar, but three-dimensional, fields from observations, linear Rossby waves were generated by a stationary source of vorticity {a twisting force in a small part of the fluid} as an exploratory computer experiment ([Figure 12](#)). The size of the forced region is about 30° of latitude. The waves indeed follow the westerly Northern Hemisphere jet. Preferred propagation into and out of the tropics occurs ([Figure 11](#)) where the zonal winds are weak or westerly, rather than the more usual easterly winds. Lines along which $U = 0$ lead to infinite values of β^* , and these 'critical lines' tend to reflect Rossby waves, after a certain amount absorption of their wave activity and momentum. Computer models are sensitive to the way such regions are handled, and to the levels of frictional damping assumed

Figure 11 (a) Mean westerly wind speed at 300 hPa in Northern Hemisphere winter. (b) Mean north-south barotropic potential vorticity gradient, $\beta - \partial^2 U / \partial y^2$. Note the large values in the mean westerly jets. (c) Effective restoring force for Rossby waves, β^* . Heavy line in (c) is a concentration of high values of β^* at critical lines. Zero lines are dotted, negative are dashed. The Greenwich meridian is marked with an arrow. From Hoskins BJ and Ambrizzi T, *Journal of the Atmospheric Sciences*, 50: 1661–1671, 1993.

Figure 12 Meridional wind anomaly at day 10 for circular heat source at 20° N, 0° E, with December–January mean flow. This is a three-dimensional model calculation, but with a wave environment dominated by the barotropic PV (Figure 11). From Ambrizzi T and Hoskins BJ, *Quarterly Journal of the Royal Meteorological Society*, 123: 919–929, 1997.

in their formulation, leading to lingering uncertainty about many features of the circulation.

While the idea of Rossby waves having preferred waveguides is attractive, a slightly different interpretation of this experiment is that the jetstream itself is prone to meandering. It has a strongly concentrated PV gradient, and when disturbed it develops intense oscillations which have both stable and unstable components. This is not quite the same thing as

a Rossby waveguide, and perhaps better describes the ‘capture’ of Rossby wave energy by the underlying circulation.

This idea has been developed extensively, and it is found that the time-averaged winter winds can actively contribute to the wave field, exhibiting barotropic instability that can resemble a simple train of Rossby waves. Thus, in the PNA pattern, describing the atmospheric response to a warm tropical Pacific Ocean energy can be added to the wave train, transferred from the large-scale circulation, en route to North America. The weakly unstable modes are not easy to sort out because of the more rapidly growing baroclinic instabilities of the system.

Energetic Eddies and Breaking Rossby Waves

The atmosphere is made more complex, however, by the great strength of the winds and the large temperature range. With winds as strong as those typically observed, nonlinear effects (neglected in the simplest theory of Rossby waves) are strong, and lead to a large-scale form of turbulence (‘geostrophic turbulence’). We have just described how Rossby waves interact with the general circulation. This goes both ways: the waves induce new and important arteries of general circulation and the circulation, through something like linear instability, generates waves and eddies.

A view of the great energy of the atmosphere is readily seen in daily satellite images. The potential vorticity field at the 320 K isentropic surface on 14 May 1992 (Figure 13) cuts through the tropopause, showing the highly convoluted path of the jet stream. Obviously this is not a ‘small perturbation to a westerly wind.’

General circulation aside, the eddies interact among themselves in ways that are not subject to the propagation rules of waves. Geostrophic turbulence {the strong interaction among eddies that are of the scale of storms and weather, and larger} obeys none of the rules of classical turbulence observed in nature: energy cascades {flows, moves} predominantly to large horizontal scale and into barotropic eddies {tall motions with flow that is similar over a wide range of altitude}. The merging of two eddies of the same sign {both either cyclonic or anti-cyclonic} is a part of this cascade, and can lead to concentration of the flow into a few, sparse, intense eddies. The ‘life-cycle’ of intensifying cyclonic storms in the atmosphere is a manifestation of this cascade toward tall eddies with reduced vertical shear and hence reduced potential energy, followed by horizontal propagation: barotropic Rossby waves propagate rapidly, and the turbulence cascade feeds energy into them. Typically the growing storm develops cut-off {closed patterns of} temperature and PV fields, whereupon it is more an eddy than a wave.

More generally, the interaction of the transient and stationary waves, as calculated from observations, is an expression of the complex mix of Rossby waves and eddies (stationary and traveling) found in the general circulation.

The chaotic development of geostrophic turbulence has similarities to the pairing of cyclones and their north-south movement, which reorganizes the larger-scale circulation. Purely barotropic turbulence also coexists with Rossby waves, and can feed energy into them: either through the jostling of

Figure 13 (a) Potential vorticity (PV) over Europe on the 3201 K surface at 1200 UT on 14 May 1992, from ECMWF analysis. The tropopause, dividing troposphere and stratosphere, cuts through the figure along the 0.5 to 1.5 contours. a pair of adjacent eddies or through distortion of an eddy by the larger-scale circulation.

When the fluid motion is very energetic, PV mixing occurs, and this directly forces changes in the large-scale atmospheric circulation by shifting momentum about. In some circumstances this can be described as a ‘breaking’ Rossby wave, in which lines of constant PV fold over sideways (still with nearly horizontal motion) and curl up.

More about Vertical Propagation

As we have seen, the defining properties of Earth’s atmosphere and ocean (and, indeed, the atmospheres of other planets) arise from the underlying rotation of the planet and its form

as an irregular sphere; to these we now add the extreme thinness and the nearly horizontal layering of air and water, with gradation from large density below to small density above. This density varies significantly over one scale height of the atmosphere, defined as $H_s = RT/g$ (R being the gas constant, T the temperature, and g the gravitational acceleration); it is typically 8 km. The layered stratification allows vertical variation of the horizontal wind, according to the thermal wind relation (see **Dynamical Meteorology: Overview**). This introduces a new class of *baroclinic* Rossby wave which propagates in all three dimensions. We now have a basis for understanding **Figure 2(b)**.

The extreme gravitational stability of these fluid layers is expressed in the buoyancy frequency (eqn [16]).

$$N = \left(\frac{g}{\theta} \frac{\partial \theta}{\partial z} \right)^{1/2} \quad [16]$$

This is the frequency of bobbing of a small air parcel, after it is given an upward or downward impulse (see **Gravity Waves: Buoyancy and Buoyancy Waves: Theory**). In the troposphere, the period $2\pi/N$ is typically 10–20 min; and in the lower stratosphere it is about 5 min. Here we use a local Cartesian coordinate system, (x, y, z) (east, north, up).

The form of the potential vorticity eqn [1] including vertical propagation is given in eqn [17].

$$\frac{D}{Dt} \left(\nabla^2 \psi + \rho^{-1} \frac{\partial}{\partial Z} \frac{\rho f^2}{N^2} \frac{\partial \psi}{\partial Z} \right) + \frac{dq}{dy} \frac{\partial \psi}{\partial x} = 0 \quad [17]$$

Here $Z = H_s \ln(p_0/p)$ is a slightly modified vertical coordinate, proportional to the log of the pressure. For waves with simple sine-wave variation east and west, and oscillating like a sine wave in time, we find a Helmholtz equation related to eqn [9] but now with respect to y and z (north and vertical). For stationary waves with mean westerly wind $U(y, z)$, and simplifying by considering N^2 to be constant, we let $\psi = \exp(ikx) \exp(Z/2H) \Phi(y, z)$ giving eqn [18a], with ν^2 and λ given in eqn [18b].

$$\frac{\partial^2 \Phi}{\partial y^2} + \frac{f^2}{N^2} \frac{\partial^2 \Phi}{\partial Z^2} + \nu^2 \Phi = 0 \quad [18a]$$

$$\nu^2 = \left[-\lambda^2 - k^2 + U^{-1} \frac{dq}{dy} \right], \quad \lambda = \frac{f}{2NH} \quad [18b]$$

Here ν^2 is the index of refraction for the waves; simple refraction occurs, in which rays bend toward regions of large index of refraction, and their paths can be sketched on a plot of ν^2 . Solutions of this equation are wavelike where ν^2 is greater than zero, and waves cannot penetrate regions where ν^2 is negative; only a small tail of the disturbances reach inside such regions. In particular, the waves can penetrate only where U falls in the range given in eqn [19].

$$0 < U < \frac{dq/dy}{k^2 + \lambda^2} \quad [19]$$

Jule Charney and Philip Drazin showed, in 1961, how in this analysis the zonal wind must be westerly and yet not too strong for stationary waves to propagate upward toward the stratosphere. The signature of this upward propagation is a three-dimensional wave-vector $\mathbf{k}$ that points downward and to the west, which means that the wave-crests are sloped

upward to the west, just as in Figure 2(b). This happens in a window of time in midwinter. It is remarkable that the very dispersive Rossby wave should, in the case of a single wave in x and t , be governed by a simple, single index of refraction (as if it were nondispersive). Tracing of the rays along which the waves propagate in the y – z plane (northward, upward) can be done immediately and easily (see model simulation in Figure 14). Errors due to east–west variations in the large-scale ‘mean’ atmosphere can be quite important and tracing of rays in all three dimensions would seem important, yet the very long wavelength east and west invalidates simple ray-tracing theory.

The upward propagation of Rossby waves into the stratosphere is particularly energetic in the Northern Hemisphere in winter, and the forces they exert act to decelerate the strong winds of the polar vortex. The important waves are very long, with just one or two wavelengths around a latitude circle. The dynamics of breaking Rossby waves and potential vorticity mixing by the turbulence that follows are a crucial part of the dynamics of the stratosphere (see **Middle Atmosphere: Planetary Waves**). Confinement of air over the wintertime pole by the strong potential vorticity gradient makes possible the chemically induced ozone hole.

Rossby Wave Forcing of the General Circulation

Transport of momentum and energy by Rossby waves and by geostrophic turbulence is a key to the ‘shaping’ of the general circulation. For example, the north–south circulation, averaged east and west, of the stratosphere, known as the Brewer–Dobson circulation, is related to strong radiative forcing, but is largely enabled by Rossby waves transporting easterly momentum upward from the troposphere. The lower atmosphere thus ‘pushes on the stratosphere above,’ and on our rapidly rotating planet this leads to both a deceleration of the polar vortex and flow at right angles and poleward. The Rossby wave force that does this has been diagnosed from observations (Figure 15).

The transmission of energy and momentum in Rossby waves has an elegant theory, with deep relations to classical physics. Potential vorticity, being conserved following air parcels (in an ideal sense, ignoring dissipation and external forcing), provides remarkable connections between the ‘stirring’ of fluid (as seen by marking it with colored smoke) and forces and momentum. These ideas can be discovered by the interested reader and he or she will be rewarded.

Concluding Remarks

There are many more manifestations of Rossby waves in the atmosphere than are described here, including ultralong modes with rapid easterly propagation, modes related to tidal forcing, and particularly the large derivative class of potential-vorticity waves involved in baroclinic growth of storms. Waves, instability, wave-induced acceleration of the mean circulation, life cycles of geostrophic turbulence, and potential vorticity mixing fill out the dynamics of the atmosphere, and Rossby waves are just the first step toward their understanding.

Finally, we must remark that ideas in science should be tested when possible by physical experiments. On a rotating platform rather like Rossby's (Figure 16), we can easily produce a 'polar β -plane' in which the steady paraboloidal free surface of water in a cylinder provides a potential vorticity gradient very much like that in the middle and high latitudes of Earth. By oscillating a small glass cylinder up and down, squashing vortex lines, we generate an energetic Rossby wave (Figure 17), most visible toward east of the wavemaker. The short waves seen there have phase propagation toward their energy source, rather like the theoretically derived waves in Figure 3. The waves also transport momentum, driving easterly flow at most latitudes (as predicted by theory), and a westerly jet at the latitude of the forcing. They coexist with turbulent eddies. Furthermore, the orange polar cap region, despite strong wave activity, does not mix with the lower latitudes. This is the 'ozone hole effect,' by which potential vorticity gradients inhibit mixing just as they promote Rossby waves.

Figure 17 Rossby waves in the laboratory, as if viewed by a satellite above the North Pole. The wave source is at the lower left, an oscillating body. There is no preexisting circulation, but the waves induce easterly flow at most latitudes, and westerly flow at the latitudes near the forcing (as seen in the dye drawn into circles). At the North Pole, the red dye remains unmixed by the strong wave activity. Courtesy of the Geophysical Fluid Dynamics Laboratory, University of Washington.

Bernard Haurwitz

Historical Notes

Large-scale waves on a rotating sphere were predicted with mathematical theory at the end of the nineteenth century by Hough and Margules. Bernard Haurwitz (Figure 18), after leaving Germany in the early 1930s, derived the essential properties of these modes in a 1937 paper. His status as 'enemy alien' in the United States in 1942 did not prevent the Army Air Corps from asking him to direct a research program on weather

forecasting. Carl-Gustav Rossby (see [Figure 16](#)) developed an elegantly simple approximation known as the β -plane, with which the derivation of the waves is greatly simplified. As so often happens in science, the full force of the earlier theory did not become apparent until long after its discovery. Rossby's influential first paper on the subject appeared in the *Journal of Marine Research* in 1939 (reminding us that these waves exist in both ocean and atmosphere). By emphasizing the simple propagation formula, Rossby successfully brought the ideas to bear on observations of the circulation at MIT in important papers in 1939, and through the war years. Before the era of computer simulation of the atmosphere, Rossby waves provided a foothold of dynamical theory in aid of weather

forecasting. Much later, in the last quarter of the twentieth century, Rossby wave dynamics has filled out like a powerful floodlight our understanding of the dark corners of atmospheric dynamics.

Solitary Waves

JP Boyd, University of Michigan, Ann Arbor, MI, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

Solitary waves are steadily translating disturbances in which nonlinearity and dispersion balance to create a disturbance of permanent form. The alternative name 'soliton' was coined because solitary waves are long-lived and elementary particle-like. Other coherent structures such as vortices or vortex pairs may exhibit a similar nonlinear persistence. Many distinct species of solitons are observed in both the ocean and the atmosphere. Solitary wave misconceptions are also reviewed.

Definition

In the narrowest sense, a solitary wave is a single, isolated wave crest, which propagates steadily without either steepening or widening. However, the concept has been broadened by the discovery of many new species of similar phenomena. Also, nonpropagating 'coherent structures,' especially vortices, have much in common with solitary waves. Thus, 'solitary wave' is no longer a phenomenon but a theme. The theme is nonlinear self-preservation of a crest or a vortex in the face of opposing, disruptive forces.

Dispersion, Frontogenesis, and the Bell Soliton

The left curve in Figure 1 is a schematic of the simplest solitary wave. It is called a 'bell soliton' because its shape resembles a church bell.

Waves are said to be 'dispersive' if the propagation speed c of a sinusoidal wave varies with the wavelength λ . It is possible to superimpose many sine waves of different wavelengths to make a bell shape, which is centered where all the crests are in phase. However, the bell shape rapidly disperses into an ever-widening patch of ever-shrinking ripples as illustrated in the upper right of Figure 1. In a marathon race, the runners are elbow to elbow at the start, but disperse into an ever-widening pack with the fastest runners in front and the slowest runners falling farther and farther

behind at the rear. Wave dispersion is the same as track-and-field dispersion: When waves travel at different speeds, the disturbance must spread over time unless some other mechanism intervenes.

One such mechanism is advective steepening. If the fluid velocity is proportional to height, then an initial bell shape will evolve a leading edge front (Figure 1). As the fast-moving tip overtakes the lower, slower fluid, the trailing (left) edge is stretched while the leading edge steepens ('frontogenesis').

In a solitary wave, dispersion and nonlinear steepening *exactly balance* so as to create a wave, which propagates *without change of shape*.

History of Solitary Waves

Solitary waves were discovered by the naval architect John Scott Russell in 1834. When a canal barge hit an underwater obstruction and stopped suddenly, Russell expected that the bow wave would dissolve into lots of little ripples through dispersion. Instead, a smooth, bell-shaped crest perhaps half a meter tall, independent of the cross-channel direction, emerged from the froth. On horseback, he followed the unchanging, steadily propagating crest for a couple of kilometers until he lost it 'in the windings of the canal.'

Russell later made solitary waves in a long, narrow water tank. Dropping a square block into the water produced a localized wave disturbance, which speedily organized itself into one or more solitary waves followed by a few small dispersing ripples.

Forty years later, Rayleigh and Boussinesq showed that

$$A(x, t) \approx \text{constant } B^2 \text{sech}^2(B[x - ct]) \quad [1]$$

where the phase speed c is proportional to B^2 , where B is a positive parameter that simultaneously controls the width, speed, and amplitude of the solitary wave.

Korteweg and deVries (1895) assumed that the wave was independent of the cross-channel direction, as approximately true both on the canal and in Russell's water tank, and also that the horizontal current was depth-independent ('shallow water approximation'). Thus, the only nontrivial spatial coordinate is down the channel. The surface height is then proportional to the solution $A(x, t)$ of the Korteweg–deVries (KdV) equation:

$$A_t + c_0 A_x + \mu A_{xxx} + \nu A A_x = 0 \quad [\text{KdV Eq.}] \quad [2]$$

where the subscripts denote partial differentiation with respect to the subscripted coordinate, and where the coefficients

Figure 1 A bell-shaped crest (left) will dissolve into little ripples under pure wave dispersion; it will steepen and eventually break if advective steepening is unopposed by dispersion. In a solitary wave, dispersion and steepening exactly balance so that a bell-shaped curve propagates steadily without change of shape.

depend on the water depth, channel width, and the gravitational constant.

Today, it is known that the KdV equation is *generic* in the sense that it can be rederived for weakly nonlinear long waves in a wide variety of physics and engineering contexts, not just water waves. For 70 years after Korteweg and deVries, however, solitary waves were only a curiosity, mentioned in textbooks out of duty rather than conviction.

Zabusky and Kruskal in 1965 numerically integrated the KdV equation on a spatially periodic domain and discovered that a large amplitude initial sine wave dissolved into a sequence of solitary waves. These peaks collided elastically (i.e., without loss of energy from the colliding pair), as robust as if they were elementary particles. Zabusky and Kruskal therefore coined the name ‘soliton’ which is today used as a synonym for solitary wave.

A couple of years later, Gardner, Green, Kruskal, and Miura discovered the ‘inverse-scattering’ method. Although the KdV equation is *nonlinear*, the inverse-scattering method is an exact algorithm, which solves the general initial value problem for arbitrary time by solving a sequence of *linear* subproblems.

The KdV equation has special solutions, which consist of N solitary waves of different sizes where N is arbitrary. Tall solitons overrun shorter solitary waves, collide elastically, and then all rematerialize in their precollision amplitudes and widths.

The general KdV solution has two parts: a finite number of solitary waves plus a dispersing wavetrain. Except for rather special conditions, such as an initial height which is nonpositive, at least one solitary wave is *always* generated, even from wildly nonsoliton initial conditions, such as the bow wave of a canal barge. The flow spontaneously either steepens or disperses so as to *evolve* an exact balance between nonlinearity and dispersion in the solitary waves even when these two competing mechanisms are wildly imbalanced initially.

The following 10 years were the Golden Age of Solitons. Envelope solitary waves, kink solitons, and other new species were discovered, each solving an inverse-scattering-solvable generic partial differential equation in (usually) one space dimension. For a time, it seemed that the inverse-scattering method was the algorithm for everything. Then the thermonuclear bomb known as Chaos theory detonated, and it became clear that inverse scattering fails for most physical systems including the three-dimensional hydrodynamic equations.

The last quarter of the twentieth century has been the Golden Age of the Generalized Solitary Wave. Many species of coherent structures *almost* satisfy the classical definition of a solitary wave. Further, nonlinear steepening can preserve vortices and other moving structures even in the absence of wave propagation. Monopoles, modons, and weakly nonlocal solitons, described below, are important quasisolitons.

Solitary Vortices: The Vortex in a Strain Field

Nonlinear self-preservation is not limited to waves. Blobs of fluid are teased out into long, stringy filaments by the ‘strain’ or ‘deformation’ field created by distant vortices, pulled apart like

Figure 2 Thin arrows: a pure straining field. A patch of vorticity-free fluid would be irreversibly contracted toward the x -axis and stretched along the y -axis. If the fluid is a sufficiently strong vortex, the patch will be deformed into an ellipse (heavy curve) with its long axis oriented at 45° to the contraction and dilation axes of the strain field. The sense of rotation within the ellipse of uniform vorticity is shown by the heavy double-ended arrows.

taffy candy. However, if the blob is a sufficiently strong vortex, its own self-interaction will preserve it. A patch of uniform vorticity will distort into an elliptically shaped vortex with its long axis at angle of $\pi/4$ to the axis of strain, as shown in 1971 by Saffman and Moore (Figure 2).

The vortex in a strain field is not in any sense a wave. Nevertheless, a vortex is a coherent, isolated structure, which is preserved by nonlinearity in the face of disruptive mechanisms.

On a rotating earth, a large vortex will drift westward because of the beta-effect – a wavelike behavior. It is then impossible to speak of ‘solitary waves’ and ‘isolated vortices’ as separate species. The coherent structure is both wave and vortex.

A History of Isolated Vortices

Smoke rings were discovered by casual observation long before there was any science of fluids. Any smoker can make a ring merely by blowing out a mouthful of smoke. The smoke is trapped in a torus of fluid, which propagates away from the mouth under its own self-interaction. The propagating torus is a vortex ring, rotating about its narrow diameter.

In the 1860s, Tait showed that a trailing smoke ring can overtake and pass through another, then slow to be passed in its turn, as in the child’s game of leapfrog. This robust survival of leapfrogging rings is reminiscent of the durability of KdV solitons under collisions that was discovered by Zabusky and Kruskal a century later. Anticipating their analogy of coherent fluid structures with elementary particles, Lord Kelvin was inspired by Tait’s experiments to create a theory that atoms were vortex rings, and molecules were interlocking vortex rings.

Around 1900, Chaplygin and Lamb independently discovered analytic solutions for a pair of contra-rotating vortices, now usually called ‘modons’ or ‘Chaplygin–Lamb dipoles.’ Three quarters of a century later, Stern and Larichev and Reznik generalized these solutions to incorporate the beta-effect. Vortex pairs form spontaneously through random near-collisions of one-signed vortices in turbulence, through injection of river and estuary flows into the oceans, and a variety of other mechanisms.

Boyd generalized modons to vortex pairs that straddle the equator in the early 1980s. For small amplitude, these modons are well-described by the KdV equation and are classical ‘bell’ solitons in longitude with the usual structure of linear equatorial waves in latitude; most of the propagation is wavy, due to the Rossby beta-effect. As the amplitude increases, equatorial modons develop pockets of recirculating fluid, just as in Chaplygin and Lamb’s solutions, and the westward propagation is more and more due to the mutual interaction of the two vortices.

One can no more say that an equatorial modon is either a wave or a vortex pair than one can assert that the color purple is either red or blue.

Periodic Generalizations of Solitary Waves: Cnoidal and Polycnoidal Waves

The adjective ‘solitary’ is as misleading as ‘wave.’ Korteweg and deVries showed that the KdV equation has an exact elliptic function solution that they dubbed the ‘cnoidal wave.’ This is spatially periodic with an arbitrary period. In the limit of small amplitude for fixed period, the cnoidal wave is an ordinary cosine function. The large amplitude cnoidal wave has narrow peaks, which are well approximated by the sech^2 shape of the solitary wave (Figure 3). The soliton is just a limiting case of the cnoidal wave.

Eighty years later, Toda proved that the cnoidal wave is the *exact* sum of an infinite number of copies of the solitary wave

where the copies are evenly spaced, one centered on each spatial period. This sum-of-solitons relationship is true even in the small amplitude regime (foreground of Figure 3) where $A(x,0)$ is also well approximated by the cosine function. This nonlinear superposition principle has since been extended to many other wave equations.

Similarly, the KdV equation has exact analytical N -soliton solutions on an unbounded spatial interval, which have been extended to spatially periodic exact solutions. These generalizations, which are ratios of multidimensional theta functions, are called ‘ N -polycnoidal’ waves where the cnoidal wave is the special case $N = 1$. Polycnoidal waves depend on N independent phase speeds. It can be proved that the general solution to the KdV equation with periodic boundary conditions can be approximated to arbitrary accuracy by a polycnoidal wave of sufficiently large N and appropriate phase speed and amplitude parameters.

Thus, solitary waves need not be solitary. This is true for solitary waves in general and not merely for KdV solutions. Because solitons usually decay *exponentially* with distance from the core of the structure, a pair of solitons can be rather close and yet have a negligible dynamic interaction.

Weakly Nonlocal Solitary Waves

If the phase speed c of a coherent structure is multivalued in the sense that there are infinitesimal amplitude waves of some wave number k that have the same phase speed as the structure, then the solitary wave will not decay to zero at large distances from its center, but will instead radiate waves of wave number k . In many cases, the amplitude of the radiation is exponentially weak so that the structure behaves very much like a classical solitary wave. Such structures are called ‘weakly nonlocal’ solitary waves (Figure 4).

Ironically, water waves, the prototype of solitons, are weakly nonlocal. The solitary wave radiates capillary waves, but these were too small for J.S. Russell to observe.

Figure 3 The KdV cnoidal wave $A(x,t)$ as a function of x (for fixed time $t = 0$) and amplitude a . For small amplitude (foreground), the cnoidal wave is sinusoidal. As the amplitude increases, the peaks become taller, narrower, and more soliton-like.

Figure 4 The ‘core’ of a nonlocal solitary wave is similar to a bell soliton, but the wave decays to small amplitude sinusoidal ‘wings’ instead of to zero.

Weakly nonlocal solitary waves are found in all branches of physics and seem to be just as common as classical, decay-to-zero solitons. Baroclinic vortices and solitons, for example, are usually nonlocal through weak radiation in the barotropic vertical mode.

A Bestiary of Solitary Waves and Coherent Vortices

Figure 5 shows the diversity of solitary waves and coherent structures. The six species illustrated are only a set of interesting creatures from a much larger zoo.

Bell solitons, such as those that solve the KdV equation, have been described above.

An ‘envelope solitary wave’ is the product of a sinusoidal ‘carrier wave’ with a slowly varying amplitude factor called the ‘envelope,’ which is dashed in the figure. The *envelope* solves the nonlinear Schrodinger equation and propagates at approximately the group velocity of infinitesimal waves of the wavelength of the ‘carrier wave.’

‘Breathers’ are solitary waves whose amplitude oscillates in time. The breather may be either stationary or propagating, but the period and amplitude of the ‘breathing’ oscillations never changes. The sine–Gordon, self-induced transparency, and ϕ^4 field theory equations also have breathers.

‘Kinks,’ also known in some contexts as ‘traveling shocks,’ occur in both inviscid models (such as the sine–Gordon equation) and viscous equations, such as Burgers’ equation and the Kuramoto–Sivashinsky equation. Viscous shocks seem a paradox since mechanical energy is being damped and yet the shocks, like solitary waves, are independent of time except for a steady propagation. The plateaus, extending indefinitely away from the shock, act as limitless reservoirs of energy to

sustain the shock. Real kinks do not extend indefinitely, but are consistent local approximations to coherent structures of finite width.

Vortices, whether monopoles or modons, are not always identified as solitary waves. If the diameter of the vortex is sufficiently small compared to the radius of the earth, then wave effects may be only a small correction to vortex dynamics. However, vortices often exhibit the same robustness and nonlinear self-preservation as KdV solitons.

Monopole vortices have vorticity which is everywhere of the same sign except perhaps for an annular ring surrounding the core. Modons are pairs of contra-rotating vortices as described earlier. These have a strong nonlinear translation, indicated by the hollow arrow in the figure, which is augmented or opposed by westward Rossby wave propagation.

Solitons and Coherent Vortices in the Ocean

In the Andaman Sea, tidal flow triggers regular trains of internal gravity solitons. These are visible in satellite photographs as long parallel streaks and are well modeled by the KdV equation.

When the Gulf Stream separates from the coast at Cape Hatteras, it develops unstable, amplifying meanders that eventually roll up into Gulf Stream rings. Most ‘cold core’ rings perish in a few months by reabsorption, but the few that drift south of the Gulf Stream live a couple of years in the Caribbean. This is an order of magnitude longer than the lifetime of a small amplitude Rossby wave of the same initial size (roughly 200 km in diameter). Similar coherent, long-lived eddies split from the Agulhas Current off South Africa.

The high evaporation of the Mediterranean Sea creates dense, salty water that flows out through the Straits of Gibraltar into the Atlantic Ocean. As it sinks to a depth of 1000 m, the anomalously hot and salty water rolls up into anticyclonic vortices called ‘Meddies.’ These spinning lens-shaped masses, perhaps 60 km in diameter and a kilometer thick, have lifetimes of half a dozen years or more.

Smaller coherent vortices, both monopoles and dipoles, are very common. Dipoles with long stems of vorticity are called ‘mushroom vortices’ from their shape. These are easily made in the laboratory merely by injecting a jet of fluid into a rotating tank. River outflows and melting at the edge of the ice pack are prolific generators of such vortex pairs, a few kilometers in diameter.

Solitary waves and isolated vortices and vortex pairs seem to be very important components of ocean dynamics. There is room here to catalog only a small subset of the rather wide range of observed species.

Figure 5 A selection of soliton species. All are snapshots at a single time except for the breather, which shows the oscillation at intervals of one-quarter of the temporal period.

Why Atmospheric Solitons Are Vertically Trapped

When a wave propagates upward into thinner and thinner air with weak or negligible dissipation, its amplitude u grows so that the energy flux remains constant even as the mass density decreases exponentially with altitude. A steady balance between nonlinearity and dispersion is impossible because the nonlinearity is *steadily increasing with height*. In contrast, the dispersion depends only upon the wavelengths of the

sinusoidal waves that comprise the wave pulse and thus does *not change* with height.

However, some waves are reflected by wind shear or static stability variations at some level, thus being trapped below the reflection height. Only such ‘vertically trapped’ waves can form solitons.

The ocean is a bounded fluid of almost constant density, so the difficulties of propagation to space and vertically increasing nonlinearity do not arise. This is one important reason why solitary waves are more readily observed in the ocean than the atmosphere.

Atmospheric Solitary Waves

New species of atmospheric solitary waves and new applications of previously studied types are inevitable. The following four examples are representatives of the diversity of ‘soliton thinking.’

Internal Gravity Waves: The Morning Glory

A low-level temperature inversion can create a layer of very stable air in the lowest kilometer or two of the atmosphere. Internal gravity waves are vertically trapped, and then can be reshaped by nonlinearity into a sequence of solitary waves. This mechanism operates all over the world. In particular such gravity solitons have been detected by Doppler radar and surface networks in Oklahoma. On the shores of the Gulf of Carpentaria in northern Australia, conditions are especially favorable to generate such soliton trains, and to further make the soliton crests visible through condensation. These trains of roll clouds are known as the Morning Glory (Figure 6).

The waveguide is leaky, so these solitary waves are ‘weakly nonlocal.’ Indeed, the upward leakage is so strong that recent articles have argued that convective forcing may be as important as soliton dynamics in sustaining the crests as they roll in from the Gulf.

Great Red Spot of Jupiter

The Great Red Spot (GRS) is an anticyclonic, eye-shaped vortex embedded in a shear zone between alternating east–west jets at about 20° S latitude on Jupiter (Figure 7). It has been spinning for at least three centuries with only minor fluctuations in amplitude and appearance. It is an isolated vortex in the sense that it is the only large feature in the shear zone. However, it cannibalizes smaller eddies that appear on the edges of the zone, and this may help to sustain the GRS against losses to viscosity and radiative damping.

A KdV theory has produced plausible agreement with observations; the eddy is both vortex and Rossby wave. Numerical models by G. Williams and P. Marcus offer a vivid explanation of GRS genesis. Generically, shear instabilities roll up into a string of vortices. Such chains of same-sign vortices are unstable to vortex mergers, and eventually a single large quasisteady vortex emerges as the end product of the instability. But Jupiter is banded with many alternating jets; why is there a strong vortex in only one of these, and only in the Southern Hemisphere?

Figure 6 Schematic of the Australian Morning Glory. Left: the vertical profile of Brunt–Väisälä frequency after convection has created a very stable, well-mixed surface layer. When sea breezes collide at night over Cape Yorke Peninsula, this excites a gravity wave disturbance, which is trapped in the bottom layer by reflection from the interlayer boundary (dashed line) where the stability changes abruptly. The disturbance spontaneously organizes into an undular bore as it propagates over the Gulf of Carpentaria. Each peak is a solitary wave, and its updrafts cause condensation (shaded). The roll clouds may extend for over 100 km perpendicular to the direction of propagation, which is indicated by the large arrow.

Figure 7 Schematic streamlines and velocity arrows of the GRS of Jupiter.

Hurricanes

Atlantic hurricanes originate through the roll-up of the shear instability of the East African jet. However, unlike classical solitary waves, hurricanes are strongly forced and damped; they perish rapidly after making landfall, strangled by the cessation of moist convection. Hurricanes are certainly coherent vortices, but the notion of ‘hurricane-as-soliton’ has generated little enthusiasm.

The reason is pragmatic. There are many similarities between hurricanes and other roll-up vortices such as the GRS of Jupiter. However, convective forcing and damping and small-scale embedded structures such as the hot towers lining the eyewall are so important to hurricane dynamics that the hurricane-as-soliton paradigm has been ineffective in forecasting or understanding hurricanes.

Atmospheric Blocking

Atmospheric ‘blocking’ is the formation of a quasistationary vortex or vortex pair over mountains which is sufficiently strong to block the usual midlatitude storm track, forcing weather systems to detour around the block. There are many

conflicting theories of blocking. However, the block is certainly a finite amplitude, quasistationary coherent structure that propagates westward against the prevailing westerlies so as to remain fixed above the mountain range. Much theoretical work has explored the idea that mountain chains are able to excite coherent blocks because the forcing is resonant: the forced solutions are very strong because they are close to unforced, finite amplitude vortex pairs (modons). Because the forcing is weak, the modon paradigm is much more useful for blocks than for strongly forced-and-damped vortices-like hurricanes.

Misconceptions

1. Solitary waves are necessarily waves.
Vortices and traveling shocks display the same nonlinear self-preservation as KdV solitons, and may move under a mixture of advection and Rossby wave dynamics.
2. Solitary waves are solitary; periodic waves have nothing to do with solitons.
Wave crests and coherent vortices may be very close *geographically* and yet have almost no *dynamic* interaction. Chains of crests that appear wavy or sinusoidal may in fact be weakly interacting solitary waves.
3. Solitary waves are small amplitude only.
This misconception was created by the derivation of the KdV and other simplified wave equations, which usually employ expansions in powers of the amplitude. However, numerical solutions show that the solitary waves do not magically cease to exist above a tiny limiting amplitude. Instead, solitons persist as a continuous family of solutions to such large amplitude that the soliton contains entrained fluid that is trapped within the structure as it propagates. 'Small amplitude' is a restriction of the mathematics, not physics.
4. Solitary waves are one-dimensional.
The KdV equation has only a single space coordinate. However, KdV theories often multiply the KdV solution, $A(x,t)$, by a function $Y(y)$ which is spatially confined because of Coriolis refraction, as true of equatorial solitary waves, or shear trapping, as in the GRS of Jupiter.
5. Solitary waves are unforced and inviscid.
Traveling shocks of Burgers' and the Kuramoto–Sivashinsky equations are solutions to *viscous* differential equations. Furthermore, weakly forced and damped nonlinear structures may be accurately approximated by unforced, undamped solitons. However, the soliton paradigm is not very useful when the forcing dominates the flow, as true of hurricanes.

The 'Leonardo–Kolmogorov Duality'

Leonardo da Vinci, who sketched turbulent streams and scribbled notes on what he called *turbolenza* in 1500, seems to have

known that turbulence could only be described (or painted!) as a mixture of coherent and random motion. Science progresses through a willful blindness to some aspects of a phenomenon to think deeply about others. (In a language of Papua New Guinea, this is 'mokita,' which means 'things we all know but agree not to talk about.')

Kolmogorov in 1941 made the first great breakthrough in turbulence by willfully ignoring the coherent structures, and pretending that turbulence is purely random.

The Voyager photographs of Jupiter showed instead what Frisch has called the 'Leonardo–Kolmogorov duality.' The Jovian atmosphere is neither completely coherent and predictable nor completely random. Instead, the 'Leonardian' GRS, which is a solitary vortex, coexists with a seething Kolmogorovian sea of billowing, fluctuating, random-appearing turbulence. The mystery of this soliton/random duality challenges our understanding today as it challenged Leonardo's pen five centuries ago.

Static Stability

Synopsis

Static stability is a property of the vertical thermal stratification of the atmosphere which acts through gravitational buoyancy forces to suppress vertical motions. Although it is defined locally, it influences all scales of motion and helps to control the weather systems and climate of the Earth. Small-scale turbulence, mesoscale motions, mountain influences, and large-scale atmospheric wind systems are all influenced by static stability.

In addition, regions of reduced static stability may become unstable in humid air masses, when the release of latent heat of condensation for ascending air creates positive buoyancy. Thus, the distribution of static stability influences the production of strong moist convection which is essential for severe weather events as well as the tropical driving of the global climate.

Introduction

Static stability measures the gravitational resistance of an atmosphere to vertical displacements. It results from fundamental buoyant adjustments, and so it is determined by the vertical stratification of density or potential temperature. It influences the dynamics of many kinds of atmospheric motions, which in turn are responsible for determining its variations.

Static stability is represented commonly by the square of the buoyancy frequency N , which plays a role in theories for flow instabilities, wave propagation, and forced motions. As summarized below, these theories apply to a wide range of spatial scales, from small-scale turbulence to convection, mesoscale motions, and large-scale circulations for which the ratio of N to the Coriolis frequency f is paramount. Finally, the stability concepts generalized to include condensation of water vapor are shown to have predictive value for prediction of severe weather organized by large-scale weather patterns.

Basic Buoyant Stability and Instability

The role of density fluctuations in a gravity field is best in the vertical component of the equations of motion. In an absolute sense, the gravity and pressure gradient forces are usually in a state of hydrostatic balance to within 1%. However, the slight imbalances account for vertical accelerations dw/dt which are often driven by buoyancy:

$$dw/dt = -\rho_0^{-1}[dp'/dz] + B \quad [1]$$

Here, w is the vertical velocity dz/dt , t is the time, $\rho_0(z)$ is the density of a static 'environmental' reference state, and a prime indicates deviation from that reference state. B is the buoyancy force per unit mass, given by $B = -\rho'/\rho_0 g$. For many buoyant motions, B is an upper bound on vertical accelerations dw/dt since the pressure gradient term tends to oppose B . The most useful approximate form for B is

$$B = (\theta'_v/\theta_{v0})g \quad [2]$$

where θ_v is the potential temperature augmented by a small (at most, a few °C) amount proportional to water vapor, reflecting the contribution of humidity fluctuations to buoyancy.

For a dry adiabatic vertical displacement δz , a parcel conserves θ_v so that $\theta'_v = -(\partial\theta_{v0}/\partial z)\delta z$. For a stable system, the squared frequency of oscillation is commonly equal to the restoring force per displacement or $B/\delta z$ in this case. Thus,

Figure 1 Simple buoyancy motions and varying environmental static stability. (a) Stable oscillation for $N = 1$. Isentropic surfaces are shown; increasing labels indicate warmer θ . Impulsive force creates initial vertical motion W (thin arrow), adiabatic displacements of θ surfaces, changes in air parcel volume (circles), and buoyancy force (vertical arrows). (b) Parcel motions for five stability conditions. Moderate stability: $N = 1$, shown in (a). Stronger stability: $N = 2$ stable oscillation has shorter period, smaller vertical displacements. Extreme stability: $N = \infty$ has no vertical displacement. Neutral stability: $N = 0$ has displacements growing linearly, with no restoring force. Unstable conditions: $N^2 = -1$ has buoyancy forces creating amplifying vertical parcel displacements.

if pressure effects are ignored in eqn [1], the simple buoyancy frequency N is given by

$$N^2 = (g/\theta_{v0})\partial\theta_{v0}/\partial z \quad [3]$$

N , also known as the Brunt–Vaisalla frequency, is determined by the vertical gradient of θ_{v0} or equivalently by the difference between virtual temperature lapse rate $-\partial T_v/\partial z$ and the dry adiabatic rate $\Gamma_d = g/c_p$. Unless conditions are super-adiabatic, θ_{v0} increases upward, corresponding to static stability. In this case, N^2 is positive and eqns [1]–[3] imply

$$d^2w/dt^2 + N^2w = 0 \quad [4]$$

It follows that the solution is a simple oscillation $w(t) = W \cos(Nt + \varepsilon)$, where W is the maximum vertical velocity amplitude and ε is a phase constant. W is a function of the initial motion $w(0)$ and buoyancy $B(0)$. $1/2 W^2$ is equal to the total energy, which is a constant as kinetic and potential energies oscillate out of phase between zero and their maximum values. The period is $2\pi/N$, typically about 10 min in the troposphere. Figure 1(a) shows the vertical oscillation, and its driving by buoyancy, which is a quarter cycle ahead of the parcel displacement δz . The buoyancy oscillation is analogous to that of a spring, so N^2 is equivalent to the ‘stiffness’ of the atmosphere when it is subjected to vertical displacements. The stiffness increases with the closeness of θ surfaces. Figure 1(b) shows that a larger stability produces a faster oscillation and inhibits the maximum vertical displacements W/N . The associated downward buoyancy forces have a maximum magnitude proportional to WN . For a limited upward displacement, the force and potential temperature deviation is proportional to $-N^2\delta z$. This corresponds to a potential temperature deficit which is a ‘lifted index’ LI of parcel stability, which has generalized use in cumulus convection.

For smaller values of static stability, the restoring buoyancy forces are weaker and the oscillations are slower. Neutral stability occurs when $\partial\theta_{v0}/\partial z$ is zero (dry adiabatic conditions); a displaced parcel with no initial buoyancy remains that way, so there is no vertical acceleration. ‘Absolute instability’ occurs when it is further reduced to a negative value (superadiabatic lapse rate). In this case, $N^2 = -|N^2|$ is negative, and the solutions to eqn [4] are exponential in time (Figure 1(b)). The growing mode ($\exp(|N|t)$) corresponds to a cooperative relation between buoyancy and motion (e.g., warm air rising) and may be thought of as the initial stage of convection. (A decaying mode ($\exp(-|N|t)$) corresponds to a mismatch of B and w (e.g., cold air rising) and so it is of no long-term consequence.) For convective motions, the increase of vertical kinetic energy is equal to the buoyancy work $\int B\delta z$, known as the convective available potential energy (CAPE) along the parcel’s vertical path. The LI for such a parcel is negative, indicating instability. (In vertically confined convective systems, a growing mode requires that thermal and viscous dissipation must be overcome, so a critical value of $|N^2|$ must be exceeded, as expressed in a critical ‘Rayleigh number’ necessary for convection.) For many applications, the distinction between θ and θ_v is of secondary importance, as is assumed in the remaining discussion.

Figure 2 Vertical temperature profiles (solid) for three categories of static stability. Temperature changes for dry and moist adiabatic parcel displacements are dashed. AU: absolutely unstable; CU: conditionally unstable (for saturated parcels); and S: absolutely stable.

Moist Instability

In a humid atmosphere, phase changes in the water content may cause instability even when N^2 is positive. In this case, a parcel conserves its equivalent potential temperature θ_e rather than θ . θ_e exceeds θ by a temperature-dependent amount depending on humidity. As an example, conservation of θ_e is consistent with upward motions leading to saturation, the release of latent heat of condensation, and the diabatic increase of θ . These ‘moist’ diabatic processes reduce the effective static stability for cloud systems. For example, the stability of a cloud layer to internal displacements depends most strongly upon $\partial\theta_e/\partial z$, with negative values corresponding typically to instability. (This criterion is used to describe the ‘potential instability,’ an often-misused concept that describes the stability of an unsaturated layer which is lifted hypothetically until it becomes a cloud layer.)

The most important example of moist processes affecting stability occurs when rising, saturated parcels in cumulus clouds penetrate a dry ‘environmental’ layer. In this case, ‘conditional instability’ may occur even when $\partial\theta_{v0}/\partial z$ is positive and the ‘dry dynamics’ of the environment are stable. This instability criterion may be expressed as $\partial\theta_{es}/\partial z < 0$, where θ_{es} is the saturation equivalent potential temperature, a known function of T and pressure p . This criterion is met if the virtual temperature lapse rate $-\partial T_v/\partial z$ exceeds the smaller moist adiabatic rate Γ_m . The result is that the unstable combination of positive buoyancy with a rising parcel occurs if a saturated parcel moves upward through a layer of air where N^2 is insufficiently positive. Figure 2 illustrates the three fundamental types of stability for an atmosphere.

The growth of cumulus clouds is overestimated by this simple parcel reasoning because updrafts require compensating subsidence of the environment. The resulting adiabatic warming decreases the relative buoyancy of the cloud. A simple ‘slice’ theory shows that the effective stability of the system is then increased for finite-sized clouds; it can be represented as a combination of the moist and dry static stabilities. Additional stabilizing influences are turbulent mixing of momentum and thermodynamic quantities between the cloud and the environment, and the effects of pressure adjustments.

Figure 3 Vertical cross section of θ from Equator to pole. Static stability is indicated by vertical closeness of θ surfaces. Left scale is pressure in hectopascal. Dark shading: Earth's topography. Light shading: boundary layer air with moisture mixing ratio exceeding 12 g kg^{-1} . Strong stability cases: ST – stratosphere, PS – polar surface, BL – boundary layer top, FZ – frontal zone, and TB – topographic blocking by mountains. Weak stability: CU – conditionally unstable tropical troposphere and ML – convectively mixed boundary layer. GFS analysis, National Centers for Environmental Prediction (NCEP: www.ncep.noaa.gov). Climatology of Static Stability

In the simplest terms, the dry and moist static stability indices depend upon vertical profiles of potential temperature and to a lesser extent on the profile of water vapor. Figure 3 shows some typical features in a vertical cross section. Strong static stability (N^2) regions are associated with isentropic surfaces that are closely spaced in the vertical, a symptom of the vertical 'stiffness.' Weak stability regions have greater spacing, and the limit of zero stability may correspond to a vertical orientation of the isentropic surface. Regions of moist unstable motions are possible where there is a conditionally unstable temperature profile and sufficient moisture supply (e.g., the tropical boundary layer).

The distribution of static stability $\partial\theta/\partial z$ can be explained first by considering the processes that change the spacing Δz of potential temperature surfaces. From the first law of thermodynamics, it is easily shown that local changes of stability are caused by (1) advection of stability from upwind, (2) (vertically) differential temperature advection, and (3) differential diabatic heating. The differential diabatic term (3) explains many basic stability features in the atmosphere. The term is proportional to dJ/dz , where J is the diabatic heating rate per

unit mass; negative J connotes cooling. This term increases the stability where J increases with height, and decreases it where J decreases with height.

Examples of diabatic influence on static stability are seen in Figure 3. The strongest stability is seen in the stratosphere, where stability is maintained by the radiative heating increase due to absorption of solar ultraviolet radiation by ozone. The tropospheric static stability is several times smaller, due especially to downward longwave radiation. Near the Earth's surface, strong stability at high latitudes is created by longwave radiative cooling, whereas weaker stability at other latitudes is driven by sensible heat from the surface. The sensible heating is concentrated in the atmospheric boundary layer, which often resembles a 'convective mixed layer' of low stability, especially over land. In the tropics, the troposphere is moist at low levels, conditionally unstable, and deep; heavy cumulus convection is prevalent and its latent heating is the essential driving of the tropical climate system.

Some of the smaller scale features in the figure are affected by adiabatic circulation processes. Term 2 includes the effect of vertical wind shear in a baroclinic region; near the Earth's surface, warm (cold) advection situations are associated commonly with stabilization (destabilization) of the lower

atmosphere by this process. This term also explains the development of strong static stability by subsidence at the top of the atmospheric boundary layer and in frontal zones.

There are seasonal and diurnal variations in stability that cannot be represented in the snapshot (Figure 3). These variations are caused by those of solar radiative forcing of the Earth's surface, which results in variations of sensible and latent heating. Broadly speaking, the static stability fields tend to shift poleward in the summer season and Equatorward in the winter season. The destabilization of the lower atmosphere is a maximum over land on summer days, while it is a maximum over the midlatitude oceans in winter.

Static Stability and Circulation Dynamics

Static stability influences the motions of the atmosphere on a range of scales and may permit waves to connect distant regions. Simple vertical buoyancy concepts are not sufficient for understanding these effects. In reality, one must also consider the coupling to horizontal winds and the ways in which pressure links the motion of different air parcels. The spatial distributions of static stability and wind determine the outcomes, which range from flow instability to various kinds of wave propagation in the horizontal and vertical.

Small-Scale Turbulence

Turbulence in the atmosphere may be caused by convection or by wind shear, and static stability is influential in each case. Ignoring moist dynamics, convection requires $\partial\theta_v/\partial z$ to be negative, which occurs most commonly when the air is in contact with a warmer Earth's surface, such as a sunny day over dry land. In such cases, N^2 is strongly negative in the surface layer (roughly the lowest 50 m), reflecting a superadiabatic lapse rate of virtual temperature. Static stability is then near neutral ($N^2 = 0$) in a deeper 'mixed layer' up to the boundary layer top. Thus, neutral boundary layers are symptoms of surface-induced convection.

Positive static stability inhibits turbulence induced by wind shear. The production of shear turbulence may be understood by imagining a layer of concentrated wind shear which, when perturbed by vertical displacements, creates a pressure feedback that amplifies the displacements of the layer. The result is mixing of fast and slow air parcels by a growing pattern of Kelvin–Helmholtz instability (KHI) motions. Obviously, the vertical restoring forces of a statically stable atmosphere will oppose the vertical components of such KHI displacements. The competition between shear instability and stable stratification is best measured by the Richardson number:

$$Ri = N^2 / SH^2 \quad [5]$$

where SH is most generally the magnitude of the vector wind shear $\partial\mathbf{V}/\partial z$. Ri is the squared ratio of the stable buoyancy oscillation frequency N to the maximum shear-induced growth rate SH . Theory and observation show that when $Ri > 1/4$, shear growth is eliminated: static stability wins, and perturbations are stable oscillations as in Figure 1. On the other hand, when static stability is reduced so that $Ri < 1/4$, the shear instability is not suppressed totally, and the perturbations may grow into turbulence.

In the free atmosphere, intense frontal zones are associated commonly with 'clear air turbulence,' despite the zones having a maximum static stability. This is because they are sloping regions of strong gradients, and Ri is reduced more effectively by the strong shear as the vertical width of the zone becomes small. The mixing by this turbulence is thought to modify the mesoscale structure of the static stability and shear near jets.

Very near the Earth's surface, strong shear is created by frictional drag, but the turbulence is limited by the surface and static stability. In such surface boundary layers, the intensity of shear turbulence is the greatest beneath the height L , the Monin–Obukhov length. L varies inversely with the stable air–surface temperature difference and static stability near the ground. Higher in the boundary layer, the turbulent fluxes are often represented by eddy mixing coefficients which are a decreasing function of Ri (and hence static stability).

Mesoscale Motions

Static stability and its spatial variations may produce complex mesoscale motions. Since wind speeds and the frequencies of weather systems are strongly subsonic, it follows that the pressure fields are in a state of 'anelastic' balance with the temperature and velocity patterns. The simplest balance involving buoyancy B is described by the three-dimensional p.d.e. $\nabla^2 p = \partial B / \partial z$, where ∇^2 is the elliptic Laplacian operator in three spatial dimensions. The buoyancy gradient term 'forces' a smooth pressure response which decreases inversely with distance. For a vertically oriented pattern of B , the pressure response is negligible, and simple buoyancy forces dominate the motion. However, a pattern of B tilted toward the horizontal produces a pressure gradient force that opposes B . Thus, static stability may be associated with motions that may or may not be in hydrostatic balance, depending on the distribution of buoyancy in the vertical plane.

The simplest tool for understanding these motions is the theory of buoyancy waves (see Atmospheric Waves). For patterns of motion and temperature with phase fronts tilted at an angle α from the vertical, the free oscillation has a frequency $\omega = N \cos \alpha$. We see that N is actually an upper limit on the frequency, corresponding to the vertical orientation for a simple buoyancy oscillation. Such motions are nonhydrostatic. Much slower oscillations occur when the wave patterns are tilted toward the horizontal, a result of the 'braking' effect of the pressure field on the buoyant parcel. These motions are nearly hydrostatic, and the waves may propagate with a nondispersive phase speed obeying

$$c_g^2 = N^2 / m^2 \quad [6]$$

where m is the vertical wave number. Strong static stability corresponds to fast horizontal wave speeds.

There are dramatic consequences of the simple frequency dispersion relation. For example, the energy of the waves is transmitted along the sloping wave front at a group speed:

$$c_g = N \sin \alpha / K \quad [7]$$

where K is the two-dimensional wave number (inverse scale) of the wave pattern. We see that the energy propagation rate

increases with static stability and with angle α from the vertical. It follows that the response to a confined impulse will rapidly spread low-frequency energy horizontally, while higher frequencies will be found immediately above and below the region. Imposed frequencies greater than N are 'evanescent': such energy cannot be propagated away from the forcing. Interestingly, the orthogonal relation between phase and group velocity vectors implies that downward phase propagation is associated with upward energy propagation.

These properties have implications for a variety of meso-scale responses of a stable atmosphere to surface heating or mountains. For example, steady airflow U over a mountain complex may be envisioned in terms of periodic forcing. The above theory for low frequencies predicts that (1) a wide mountain may cause upwind 'blocking' of low-level air with high static stability and (2) motions over the mountain are nearly in hydrostatic balance. The theory for higher frequencies suggests that very narrow mountains do not disturb the flow far above the mountain, but an intermediate mountain width yields a complex pattern of vertically propagating wave patterns extending upward and downwind of the mountain. In order for energy to propagate upward, the wave fronts must tilt upwind with increasing altitude and the waves transport wind momentum down into the mountain. An example is shown in Figure 4.

Static stability and wind variations influence the vertical fluxes of mesoscale wave energy and momentum which may

Figure 4 Streamlines and θ surfaces for flow over an isolated ridge. Upwind conditions have high static stability below 3 km, so $P(z)$ decreases upward. Wind speeds vary along streamlines in proportion to closeness of streamlines. Proceeding from the left, note the slowing of air on the upwind side, strong downslope wind, vertically tilted flow pattern, downwind jump, and lee waves trapped in the stable layer. Shading denotes possible clouds due to lifting of moist layers. Reproduced with permission from Houze, R.A. Jr., 1993. *Cloud Dynamics*. Academic Press, San Diego (Figure 12.9). Courtesy of Durran, D.R., 1986. Another look at downslope windstorms, Part 1. *Journal of the Atmospheric Sciences* 43, 2527–2543.

link the upper atmosphere with the surface. For example, the vertical structure of the steady response with horizontal wave number k is governed by a propagation coefficient:

$$P(z) = [N^2/U^2 - k^2] \quad [8]$$

The wave profile 'propagates' vertically only when P is positive, or when static stability makes the Scorer parameter N^2/U^2 sufficiently large. The vertical wave number is then $P^{1/2}$. Variations in stability or wind will cause $P(z)$ to vary, which corresponds to wave refraction in the vertical plane. Two categories of phenomena result, depending upon whether $P(z)$ decreases or increases with height.

If stability decreases with height, then $P(z)$ may become negative, and the wave may be reflected downward. Since the rigid Earth is also a reflecting surface for the wave vertical motion, the mountain-induced wave energy may become trapped in this layer. In this case, intense downslope winds and resonant 'lee' waves are possible. Other wave mechanisms, such as wave absorption at a critical layer where $U = 0$, depend more strongly on the wind profile.

In the other extreme, weak static stability in the boundary layer causes $P(z)$ to increase with height above the surface. A common idealization is a mixed layer ($N^2 = 0$) capped at height H by a sharp inversion of strength $\Delta\theta_v$. In this case, horizontal scales larger than H are hydrostatic and move with speeds of 'shallow water' gravity waves obeying

$$c_G^2 = [g'H] \quad [9]$$

We see that $g' = g(\Delta\theta_v/\theta_v)$, the 'reduced gravity' parameter for the inversion, plays an analogous role to static stability for these hydrostatic motions. An example of this kind of motion is the propagation of a gust front, the leading edge of thunderstorm outflow in the boundary layer. Another example is where this kind of air layer is forced to flow over a mountain at speed U ; the inversion stability appears inversely in the Froude number $F = U^2/(g'H)$. This number represents a competition between the flow inertia and the inversion stability or equivalently between advection by U and gravity wave propagation c_G . Values exceeding $O(1)$ may be associated with blocking on the upwind side of mountains and strong downslope winds and hydraulic jumps on the downwind side. A similar definition of F is useful for a stably stratified atmosphere encountering a mountain of height H^* : $F = [U/NH^*]^2$.

Large-Scale Circulations

Large-scale circulations are those of large horizontal dimension, associated with low frequencies and hydrostatic balance. For such motions, static stability and the rotation of the Earth are important. Coriolis effects limit horizontal parcel motions in a fashion somewhat analogous to the buoyancy oscillation. The natural frequency of this 'inertia oscillation' is simply the Coriolis parameter f , which is about 100 times smaller than N . Thus, large-scale dynamics is ruled by the two fundamental frequencies of geophysical fluid dynamics: N and f . The most important large-scale flow variable is the combination known as the potential vorticity:

$$q = (f + \epsilon)N^2 \quad [10]$$

which is proportional to both the absolute vorticity of the winds and the static stability. Two frequency classes of large-scale waves are possible. The higher frequency class is inertio-gravity waves that obey

$$\omega^2 = f^2 + N^2(k^2/m^2) \quad [11]$$

Static stability is seen to increase the minimum frequency f . These motions are never in a state of geostrophic balance, so they play an important role in the transient adjustments to thermal and mechanical forcing of the atmosphere. Vertical propagation of wave energy occurs only when frequency ω exceeds f . For example, diurnal atmospheric tides propagate vertically only Equatorward of 30° latitude.

Horizontal energy propagation is highly dispersive as a result of the Coriolis term: the largest scales propagate energy very slowly, while the smallest scales do so at the fast gravity wave speed c_G . The separation between large and small horizontal scales occurs at

$$\lambda = c_G/f = (N/f)m \quad [12]$$

known as the Rossby deformation radius.

The deformation radius is the natural horizontal scale for large-scale atmospheric dynamics. From eqn [12], it is the distance traveled by a gravity wave in the time (f^{-1}) required for Coriolis forces to deflect the velocity. It represents the spatial scale for adjustment of wind and pressure to geostrophic balance. This scale of adjustment increases with the static stability parameter N , and it decreases with rotation f .

The lowest frequency class of large-scale dynamics is that of quasi-geostrophic (QG) dynamics for which ' $\omega \ll f$ ' (see **Dynamical Meteorology: Quasigeostrophic Theory**). These motions are always near a state of geostrophic and hydrostatic balance, and are influenced strongly by static stability and the Earth's rotation. The QG form of the potential vorticity corresponding to eqn [10] has a variable part proportional to

$$q^* = \left\{ \bar{N}^2 \nabla^2 p' + f^2 \partial^2 p' / \partial z^2 \right\} \quad [13]$$

The response of p' to thermal or vorticity forcing is determined by eqn [13], which is a three-dimensional Laplacian in coordinates that are stretched vertically according to N/f . It follows that point forcing yields an elliptically shaped response, with the major axis lying in the direction of least resistance. For example, large static stability of the stratosphere yields responses that are stretched horizontally and compressed vertically. For a given vertical scale, this property implies a horizontal influence distance equal to the deformation radius. For a given horizontal scale L , it implies a vertical influence distance called the Rossby depth, given by $H_R = (f/N)L$, so that increasing the stability decreases the vertical coupling distance H_R .

Similar considerations may be applied to the QG 'omega equation' to distinguish the total response to various patterns of thermal and vorticity forcing, illustrating the crucial importance of static stability on large-scale dynamics through the ratio N/f . There are obvious global implications, since f is small at low latitudes. Two major regimes of large-scale atmospheric circulation are the result. For example, QG instability theory indicates that baroclinic wave and cyclone growth are possible only at mid-high latitudes. Hence the tropics are less variable, except in concentrated areas of moist

convection (such as tropical cyclones) where conditionally unstable air lowers the effective ratio N/f . Similar arguments account for the difference among the atmospheric circulations of other planets.

Static Stability Variability: Phenomena and Prediction

The previous static stability concepts have application to many variable phenomena in the atmosphere, particularly near the earth's surface and in combination with other variables such as water vapor.

Temporal fluctuations of static stability occur on time scales from hours to years. For example, the atmospheric boundary layer over land responds strongly to the diurnal solar cycle as it experiences surface heating during the day and cooling by longwave radiation at night. The static stability consequently is a minimum in the lower daytime atmosphere and is a strong maximum in a thin (e.g., 200 m) nighttime boundary layer. As a consequence, low-level sources of natural gases or man-made pollutants are trapped near the ground during the night, a result of suppressed turbulence and weaker winds. These products are then vigorously dispersed to higher altitudes during the afternoon, typically by convection into a deeper boundary layer (e.g., 1 km) or even the free troposphere. Spatial differences in diurnal boundary layer heating/cooling are found near coastlines and sloping terrain: (1) The daytime 'sea breeze' along coastlines is a flow of relatively cool, stable air inland from over the water. (2) The nighttime 'katabatic wind' is a downhill flow of cool, stable air which can accumulate in stagnant pools in valleys. (3) Over flat land, strong convective rains storms often produce 'downbursts' of cool air which spread horizontally as a stable 'pool,' following a leading edge 'gust front' which can produce damaging winds.

The annual cycle of temperature and stability is strongest in middle and high latitudes, where the solar energy flux has its most extreme seasonal changes, and where 'synoptic' weather systems create variability of temperature and stability over periods of days. These traveling systems result from the instability of the intense baroclinic zones separating polar air from subtropical air. These typically consist of a time progression of warm, weakly stable air masses, low-pressure cyclonic winds, cold, stable air masses, and high-pressure anticyclonic winds which are characteristic of the Norwegian synoptic weather model. (Figure 5 illustrates the spatial differences of static stability for a springtime weather pattern over the US when the synoptic systems organized large areas of convective storms.) The surges of polar air in wintertime weather systems amount to a downward 'slumping' of cold air domes as they propagate toward the equator, increasing the low-level static stability following the passage of cold fronts. The slumping process is a manifestation of the conversion of potential energy to kinetic energy of winds in large-scale weather systems and an increase in overall tropospheric static stability.

Synoptic wind patterns typically create patterns of moist convective stability due to the destabilizing advection processes discussed earlier, as well as the transport of water vapor from source regions. Since all of these processes are represented in numerical weather and climate models, a byproduct of the

systems and climate of the Earth. In the Earth's atmosphere, radiation and surface energy fluxes act to create three main categories of static stability.

1. *Strong stability*: The stratosphere is the most extensive example. Strong stability there encourages the vertical propagation of forced planetary waves through westerly winds regions, but it suppresses the growth of synoptic-scale circulations and convection.
2. *Weak static stability*: The troposphere is the atmosphere's dominant region of lesser, more variable static stability. As a result, instabilities may produce weather systems on a range of scales. For example, baroclinic wave circulations create variable weather in middle and high latitudes, and conditional instability may be realized as moist convection. Moist convection may be organized on the global scale (e.g., Hadley and Walker circulations), the synoptic scale (e.g., tropical cyclones), or the mesoscale (deep cumulus convection and severe weather). The static stability for dry processes may be strong enough to allow mesoscale mountain influences on the upper atmospheric wind or to suppress small-scale shear instability which would otherwise produce clear air turbulence.
3. *Static instability*: The energy balance of the Earth system requires that the Earth's surface provides energy to the atmospheric boundary layer. This is often associated with static instability, dry convective motions, and sensible heating. Neutrally stable conditions are also very common, in which case turbulence transports latent energy away from the surface, enhancing the possibility of subsequent conditional instability.

In summary, the three regimes of static stability account for much of the variety of weather and climate. Ultimately, the various kinds of circulations feedback on the static stability field itself, leading to increased complexity of its space-time variability.

Finally, looking ahead to the time scales of years, the prospect of a warmed climate is consistent with a changed

energy budget that requires the surface to release more energy upward into the boundary layer. The energy increases will be in the form of both sensible (thermal) energy and latent energy of water vapor. These changes will inevitably tend to reduce the static stability, either in the frequency of stable conditions, or in its intensity. These changes are expected to affect many weather systems, including precipitation events and storms.

Introduction

The term stationary waves refers to the zonally asymmetric features of the time-averaged atmospheric circulation. They are also referred to as standing eddies, where standing refers to the time averaging over a month to season, and eddy is a generic term for zonally asymmetric patterns. The zonal asymmetries of the seasonal circulation are particularly interesting because they occur despite the longitudinally uniform incidence of solar radiation on our planet. Stationary waves must arise, ultimately, due to asymmetries at the Earth's surface – mountains, continent–ocean contrasts, and sea surface temperature asymmetries. Understanding precisely how the stationary waves are generated and maintained is a fundamental problem in climate dynamics.

Stationary waves have a strong effect on the climate through their persistent northerly and southerly surface winds, which blow cold and warm air. Advection of moisture by the stationary wave flow contributes to hydroclimate variations over the continents. Beyond their direct advective impact, stationary waves control the location of stormtracks – the preferred paths of synoptic weather systems in the midlatitudes, and the zone of tropical–extratropical interaction in the subtropics. Stationary waves are important also on longer time scales, since interannual climate variability projects substantially on the zonally asymmetric component of the flow. Finally, stationary waves contribute significantly to the maintenance of the complementary zonally symmetric circulation, in both climatological and anomalous states; the contribution is through quadratic fluxes of meridional momentum and heat. Stationary waves are thus a fundamental feature of the general circulation of the troposphere.

Observed Structure

Stationary waves are stronger in the Northern Hemisphere because of greater orography and continentality. Wave amplitudes in the Northern Hemisphere are largest during winter, modest during the transition seasons of spring and autumn, and weakest during summer. The Southern Hemisphere stationary waves and their seasonal variation are substantially smaller in comparison.

Northern Hemisphere Winter Structure

Because of the geostrophic balance condition, stationary waves in the upper-level flow can be conveniently displayed using the height of the 300 hPa pressure surface. The geostrophic wind blows along the height contours, with lower heights to the left in the Northern Hemisphere, and with a speed proportional to

the gradient of the height field. The height of the 300 hPa surface varies considerably with latitude and longitude (**Figure 1(a)**), with the mean height being close to 9 km. The polar vortex is clearly recognizable in this projection. The vortex is due to insolation and planetary rotation, both zonally symmetric inputs, but the vortex has notable departures from symmetry: troughs over northern Canada and western Siberia, and ridges over the eastern Atlantic and Pacific. (The zonally asymmetric component of the field which highlights the troughs and ridges is shown later, in **Figure 2(a)**). The regions where the height contours are close together correspond to strong westerly (coming from the west) jets: the Asian–Pacific and North American jets.

Stationary waves at the Earth's surface can be identified using the sea-level pressure field, which in elevated areas is the surface pressure reduced to sea level. The lightly shaded regions in **Figure 1(b)** are surface lows, and the dark regions are highs. Lows are found over both ocean basins, the Aleutian Low in the Pacific and the Icelandic Low in the Atlantic. The Aleutian Low is centered off the tip of the Aleutian Islands chain, and the counterclockwise flow around the low brings southerly marine air to coastal Canada and Alaska, lessening the severity of the winter season. To the south of the Icelandic Low is a high-pressure center known as the Azores High. Strong onshore surface flow occurs between the Icelandic Low and the Azores High, again lessening the severity of coastal winters in Europe. Much higher surface pressure can be found over central Asia in a center called the Siberian High. Between the Siberian High and the Aleutian Low is a region of strong northerly flow, which brings down colder air and lowers near-surface temperature along the east coast of Asia. The winter sea-level pressure field can be broadly characterized as being high over the continents and low over the comparatively warmer northern oceans. Since sea-level pressure is related to column temperature, vertical coherence of the continent–ocean temperature contrast in the lower troposphere is key, as discussed later.

The stationary wave pattern changes considerably between the surface and 300 hPa, and these changes are highlighted in **Figure 2**. The top panels show eddy heights at the 300 and 850 hPa levels, revealing the troughs and ridges. These features are displaced westward with increasing height, i.e., westward tilted, assuming that the same features are being tracked at the two levels. The low-level trough over the Pacific is positioned 15–20° westward of the Aleutian Low, and gives way to a trough centered on the east Asian coast at 300 hPa, which is associated with the Asian–Pacific jet. The 850 hPa trough over the North Atlantic is likewise shifted relative to the Icelandic Low, and migrates further westward towards Hudson Bay at upper levels; it brings cold Arctic air into the central and eastern United States and Canada. The low-level feature over Eurasia (**Figure 2(b)**) is more definitely linked to the surface Siberian

Figure 1 (a) Average height of the 300 hPa pressure surface in northern winter months (December, January, February, and March: DJFM). The average is over 20 winter seasons (December 1979 through March 1999), and is computed from the reanalysis fields produced by the US National Center for Environmental Prediction (NCEP). The contour interval is 100 m. (b) Average sea-level pressure (SLP) for the same months and years, with a contour interval of 5.0 hPa. Sea-level pressure data come from Trenberth's analysis, which is archived at NCAR. Dark (light) shading represents values above 1015 hPa (below 1010 hPa). The letters 'L' and 'H' designate the prominent centers of action: the Aleutian Low, Siberian High, Icelandic Low, and the Azores High. Map domain begins at 20° N.

High, but there is no corresponding feature of significance present at the upper level – in contrast with the vertically coherent structure of the Azores High.

The vertical structure of stationary waves is plotted in Figure 2(c) and (d), which are cross-sections of the eddy

height field at 40° N and 60° N. The shading in these panels depicts the eddy temperature field. (In hydrostatic balance, this is the vertical derivative of the height field in $\log(p)$ coordinates.) These plots allow for the tracking of features. The northern section shows the pronounced westward tilt of the east Asian trough, the Rocky Mountain ridge, and the Azores High. The tilt is a consequence of meridional temperature advection by the associated geostrophic wind, which induces cooling to the west (east) of the low (high). Interestingly, connection with the prominent surface features is not strong, except in case of the highs. The Aleutian and Icelandic Lows, in particular, are quite shallow ($p \geq 800$ hPa), exhibiting little connectivity to the westward displaced upper-level troughs. The southern section (40° N) nicely reveals the limited vertical extent of the Siberian High, in contrast with the deep structure of the Azores High.

Comparison of the two cross-sections indicates a striking difference in vertical variation of the eddy heights, particularly in the Eastern Hemisphere. In the northern section, the wave amplitude keeps growing with height up until the tropopause, and even beyond. The structure is indicative of upward propagation of stationary wave energy into the polar lower stratosphere. (Note that the wave's phase is stationary, so the phase velocity is zero, but its group velocity – the velocity of energy propagation – is not zero.) In contrast, the 40° N structure is indicative of trapping of wave energy within the troposphere. The eddy height at the 10 hPa level, displayed using shaded contours in Figure 3, reveals the presence of a large-amplitude stationary wave at an altitude of nearly 30 km. The zonal wavelength of this pattern is evidently close to the circumference of the latitude circle, i.e., the largest possible. Both observations and theory (see **Dynamical Meteorology: Rossby Waves**) suggest that disturbances of such large wavelengths can propagate into the stratosphere. The wave pattern in Figure 3 moves the center of the polar vortex away from the geographical pole and reduces the strength of the vortex.

Equatorial westerly duct

An important circulation feature in the deep tropics during northern winter is the presence of strong upper-level westerlies ($\sim 10 \text{ m s}^{-1}$) over the Pacific and Atlantic longitudes. This is notable because the equatorial belt is otherwise occupied by easterly winds. Zonal winds at 200 hPa are shown in Figure 4(a), with the easterly region shaded. A vertical section at the equator (Figure 4(b)) shows westerly zones to be confined to the near-tropopause region (100–300 hPa), with maximum values ($\sim 15 \text{ m s}^{-1}$) at 200 hPa. The origin of equatorial westerly zones is not well understood, but their absence in northern summers and El Niño winters suggests that their occurrence is linked to the absence of strong convection in the central equatorial Pacific and Atlantic longitudes.

Rossby wave propagation theory (see **Dynamical Meteorology: Rossby Waves**) suggests that tropical easterlies are an effective dynamical barrier, shielding the equatorial zone from the influence of midlatitude perturbations. Openings in this barrier, or westerly ducts, thus provide a conduit for equatorward penetration of midlatitude waves during northern winter – a timely opening, since the midlatitude stationary and transient wave activity is most vigorous in winter. Interaction between midlatitudes and the equatorial zone can impact convection and

Figure 2 (a) Eddy height at 300 hPa during northern winter (DJFM), or height of the 300 hPa pressure surface after subtracting the zonal average. The contour interval is 50 m, with dark (light) shading for positive (negative) values in excess of 50 m. (b) Eddy height at 850 hPa for the same period, with a contour interval of 25 m and dark (light) shading for positive (negative) values in excess of 25 m. The thick contours in b enclose regions where the surface pressure is less than 850 hPa. In these regions, the pressure surface is interpolated below ground. (c and d) 1000–100 hPa zonal–vertical cross-sections of eddy height and temperature at (c) 60° N and (d) 40° N. Contour interval for eddy height is 50 m, and dashed contours represent negative values. Eddy temperature is plotted in 3 K contours with dark (light) shading for positive (negative) values in excess of 3 K, and zero contours suppressed. ‘SH’, ‘AL’, ‘IL’, and ‘AH’ are the surface lows and highs of Figure 1(b).

water vapor distribution in the tropics and subtropics. Lateral mixing from extratropical intrusions can also influence tracer transports.

Northern Hemisphere Summer Structure

The northern polar vortex is much weaker in summer than in winter. The summer vortex is shown at the 150 hPa level in Figure 5(a), and is evidently quite symmetric. It also lacks the tight meridional gradients that characterized the winter vortex. A somewhat higher level was chosen for displaying the summer pattern in order to capture fully the divergent monsoonal flow and accompanying rotational circulations over the warmer landmasses. The upper-level asymmetries include the very prominent anticyclone over Tibet, and troughs over the subtropical ocean basins which are easier to appreciate in the eddy height plots, shown later.

The summertime sea-level pressure (Figure 5(b)) has almost a reversed winter structure. Two subtropical anticyclones of comparable strength are present in the ocean basins, underneath the upper-level troughs. They are referred to as the Pacific High and the Bermuda High. The Bermuda High is the summer equivalent of the Azores High, which expands while the Icelandic Low retreats northward during the transition from winter to summer. The Pacific sector undergoes a similar winter to summer transition. The subtropical anticyclones constitute the descending branch of the regional Hadley cells which are driven by deep convection in the tropics. Descending motions induced to the north-west of subtropical monsoonal heating may also contribute to anticyclone development.

Over the continents, sea-level pressure is low during summer. A large region of low sea-level pressure is present over Asia beneath the Tibetan anticyclone (which is actually

Figure 3 Average height of the 10 hPa pressure surface in northern winter (DJFM). Thick contours show the height field in 500 m increments. The eddy height is plotted at 100 m intervals, with dark (light) shading for positive (negative) values in excess of 100 m. The zero contour for eddy height is suppressed.

centered over northern India). The continental-scale anticyclone is an integral element of the Asian monsoon circulation, being the rotational response to deep heating.

The cross-section of eddy height at 30° N (Figure 5(c)) shows the internal baroclinic structure that is typically produced

by deep heating in the tropics. The Tibetan anticyclone reaches maximum amplitude at 150 hPa, the level displayed in Figure 5(a). Over the oceans, the structure is also baroclinic, but the Pacific and Bermuda Highs are evidently shallow features – although not as shallow as their winter counterparts in Figure 2(c). The strong positive temperature centered over the Tibetan plateau is caused by latent heat release in the monsoon rains. On the other hand, negative temperatures over the Pacific and Bermuda Highs are produced, in part, from the long-wave radiative cooling to space.

The eddy height fields during summer are displayed in Figure 6. The Tibetan anticyclone is the prominent feature at upper levels. Baroclinic structure is evident in the Northern Hemisphere, with upper-level troughs positioned over the subtropical highs. Also evident at the upper level is a weak ridge over North America that is associated with the local monsoon system, which includes the Mexican monsoon. The western edge of the Bermuda High produces low-level southerly flow, which brings in significant amounts of moisture from the Gulf of Mexico into the US Great Plains. A notable low-level feature in the Southern Hemisphere is the Mascarene High centered south of Madagascar, which generates strong easterlies along its northern flank (recall that the flow around a Southern Hemisphere High is counterclockwise). After turning northward along the African coast and crossing the Equator, this flow evolves into the south-westerly monsoon flow over the Arabian Sea.

In the Asian monsoon circulation, equatorial and cross-equatorial flows play an important role, and these cannot be appreciated in the height field, since the geostrophic relationship breaks down at the Equator. The summer circulation

Figure 4 (a) The 200 hPa zonal wind in northern winter (DJFM), contoured in 10 m s^{-1} intervals. Regions where the zonal wind blows from the east are shaded. (b) Zonal-vertical cross-section of zonal wind at the Equator, contoured in 5 m s^{-1} increments, with shading for easterly regions. Top level in (b) is 50 hPa.

Figure 5 (a) Average height of the 150 hPa pressure surface in northern summer months (June, July, and August: JJA). The average is over 20 summer seasons (June 1980 through August 1999), and is computed from NCEP reanalysis. The contour interval is 100 m. (b) Average sea-level pressure for the same months, plotted as in Figure 1. The letters 'L' and 'H' designate the prominent centers of action: the Bermuda High, the Pacific High, and the broad region of low pressure associated with the Asian monsoon. Map domain begins at 15° N. (c) The 1000–100 hPa zonal-vertical cross-section of eddy height and temperature at 30° N, with contours and shading as in Figure 2(d). 'TA' gives the location of the Tibetan anticyclone, which is enclosed by the 14.3 km contour near the top of panel (a).

figures are thus complemented with a vector-wind plot at 850 hPa (Figure 6(c)); only the zonally asymmetric components of winds are plotted. Strong cross-equatorial flow occurs along the east coast of Africa, bringing moisture to the Asian continent. Easterly flow is found all along the Equator, particularly along the southern flank of the Pacific and Bermuda Highs.

Southern Hemisphere Stationary Waves

The Southern Hemisphere has much less land than the Northern Hemisphere, resulting in weaker asymmetries at its lower boundary. A more zonally symmetric circulation, with smaller-amplitude stationary waves, is thus expected. Due to the larger fraction of ocean, the seasonal cycle will also be muted. The seasonal change in surface temperature, for example, will be smaller than in the Northern Hemisphere.

The southern vortex is shown during the December–March (southern summer) and June–August (southern winter) periods in Figure 7. As before, the winter vortex is shown at 300 hPa and the summer one at the higher 150 hPa level. Thick lines mark the height contours while the shaded region shows the corresponding eddy height patterns. Note that in the Southern Hemisphere the flow around a low is clockwise rather than counterclockwise. The southern vortex is considerably more symmetric than the northern one. Eddy heights are thus smaller, and contoured at 25 m in both summer and winter (Figure 7). The summer and winter patterns are both dominated by the wave number 1 component in the high latitudes

so that opposite along a latitude circle have opposite polarities. The wave component exhibits similar phase and amplitude structure in the two seasons, indicating a significant role of Antarctic orography in its forcing. The subtropics shows greater seasonality, with a ridge over northern Australia in summer; this upper-level feature is linked to the Australian monsoon outflow.

The extent of zonal asymmetries at the surface is examined using sea-level pressure which is contoured with a 2.5 hPa interval as opposed to 5.0 hPa in the Northern Hemisphere. The summer distribution (Figure 7(c)) is much like the one in the Northern Hemisphere (Figure 5(b)), with high-pressure cells occupying the midlatitude ocean basins. In summer, the subtropical highs are interrupted by continental heat lows, caused by the warmer land temperatures. The winter sea-level pressure (Figure 7(d)) is more zonally symmetric, unlike the Northern Hemisphere where asymmetries are most pronounced during winter (cf. Figure 1 and Figure 2). A prominent feature of the southern winter pattern is the Mascarene High extending from Africa to Australia, which generates strong south-easterly flow along its northern flank. Its linkage with south-westerly flow over the northern Indian Ocean and Asian summer monsoon can be seen in Figure 6(c).

The vertical structure of Southern Hemisphere stationary waves is shown in Figure 8 at 30° S in summer and 60° S in winter – the latitude of the subtropical highs and the polar wavenumber 1 pattern, respectively. Contour intervals in Figure 8(a) are 10 m for height and 1.5 K for temperature, as

Figure 6 Eddy height at (a) 150 hPa and (b) 850 hPa during northern summer (JJA), with a contour interval of 25 m and dark (light) shading for positive (negative) values in excess of 25 m. (c) Eddy wind vectors at 850 hPa. Regions where the eddy wind speed is in excess of 5 m s^{-1} are shaded, and the longest arrow represents a wind speed of 18 m s^{-1} . Eddy winds with speeds below 2 m s^{-1} are suppressed. As in (b), the thick closed contours in (c) surround mountainous regions where the surface pressure is less than 850 hPa.

opposed to 50 m and 3.0 K in northern summer (Figure 5(c)). As in the Northern Hemisphere, the subtropical highs have a baroclinic structure with upper-level troughs superimposed on surface highs. The heat lows over Australia and southern Africa are quite shallow and intense: this is typical of arid regions where rainfall and mid-tropospheric latent heating do not occur in response to the surface heat low. The winter height and temperature structures (Figure 8(b)) are plotted using 25 m and 1.5 K intervals, as opposed to 50 m and 3.0 K in northern winter (Figure 2(c, d)), due to their relative weakness. The southern winter pattern evidently changes little with height. There is much less westward tilt in comparison with the northern winter structure (Figure 2(c)), indicating less upward propagation of wave energy. Although westerlies are necessary for upward propagation, theoretical considerations suggest that propagation is hindered by the presence of excessive westerlies

(westerlies exceeding the Rossby critical velocity), the southern winter vortex is substantially stronger than its northern counterpart (cf. Figure 1(a) and Figure 7(b)); note the larger contouring interval in the latter figure).

Transience in the Atmosphere

The above review of stationary wave structure does not convey the extent to which these waves are representative of the instantaneous circulation. For example, how stationary (or transient) is the upper-level circulation during northern winter? Can the stationary waves be ‘seen’ on synoptic weather charts? The degree to which these charts depart from the climatological pattern is a measure of the strength of the transient flow. Transient activity is estimated in northern winter in Figure 9

Figure 7 (a) Height of the 150 hPa pressure surface in the Southern Hemisphere during DJFM months (southern summer). (b) Height of the 300 hPa surface during JJA months (southern winter). Thick solid contours show the total height field in 200 m increments, while thin contours represent the eddy height. The contour interval for eddy height is 25 m, with dark (light) shading for positive (negative) values in excess of 25 m. The zero contour for eddy height is suppressed. (c, d) Sea-level pressure for (c) DJFM and (d) JJA months, in 2.5 hPa increments, with dark (light) shading for values above 1015 hPa (below 1012.5 hPa). Map domain is from the Equator to the South Pole. Sea-level pressure values over Antarctica are unreliable and hence suppressed.

Figure 8 Zonal-vertical cross-sections of eddy height and temperature in the Southern Hemisphere at (a) 30° S in DJFM and (b) 60° S in JJA months. In (a), the contour interval for eddy height is 10 m, with dashed contours for negative values. The contour interval for eddy temperature in (a) is 1.5 K, with dark (light) shading for positive (negative) values in excess of 1.5 K, and zero contours suppressed. In (b), contour intervals for eddy height and temperature are 25 m and 1.5 K, respectively, with plotting conventions as in panel (a).

Figure 9 (a) Spatial correlation between the instantaneous (00UTC) and climatological 300 hPa eddy heights during 1980/81 (solid curve) and 1989/90 (dashed curve) winters. Correlations are area weighted and include height data from 20° N to the north pole. (b) 300 hPa eddy height on 1 February 1981, when the spatial correlation was 0.74. (c) Eddy height on 16 February 1990, when the correlation was 0.29. In (b) and (c), the contour interval is 100 m (twice the interval in Figure 2(a), with dark (light) shading for positive (negative) values in excess of 100 m.

because it is expected to be strongest in this season. The greater vertical shear of the thermally balanced Asian–Pacific and Atlantic jets in winter makes them prone to hydrodynamic instability, which in the context of geostrophic flows is called baroclinic instability. Baroclinic instability produces transient disturbances on subweekly time scales.

The extent to which the stationary wave structure is representative of instantaneous flow is depicted in Figure 9 by projecting the daily, instantaneous (00UTC), 300 hPa circulation on the climatological wave pattern (Figure 2(a)) during the winters of 1980/81 and 1989/90. Correlation – a measure of the structural similarity of the two maps (without regard to amplitude) – is plotted on the y-axis. The correlation ranges from 0.2 to 0.8 in these winters, indicating that the climatological pattern accounts for up to 65% of the spatial variance. High correlation is however achieved only on a few days in each winter. More typically, the correlation is 0.5 and 0.6 between. Interestingly, the correlation drops and recovers over a 2–3 week period, 1–2 times each winter, revealing the establishment time scale of the climatological pattern. Dynamical analysis of such episodes, especially of the recovery phase, can shed light on the establishment mechanisms of stationary waves.

The question of whether the climatological wave pattern can be ‘seen’ on synoptic charts is addressed in Figure 9(b) and (c), which show the instantaneous (00UTC) wave pattern on two days: 1 February 1981, when the spatial correlation is high (0.74; Figure 9(b)), and 16 February 1990, when the correlation is low (0.29; Figure 9(c)). The climatological pattern (Figure 2(a)) can be clearly recognized in the former plot, but not in the latter. Even when structurally similar, the patterns

can evidently have very different wave amplitudes; the contour interval is 50 m in Figure 2(a) but 100 m in Figure 9(b).

Forcing of Stationary Waves

Stationary waves are generated, ultimately, by the zonal asymmetries at the Earth’s surface: orography, continent–ocean contrasts, and sea surface temperature gradients. Through dynamic and thermodynamic interactions with the zonal-mean flow, and subsequent mutual interactions, surface inhomogeneities produce zonally asymmetric circulation and precipitation features at upper levels. Comprehensive numerical models of the atmosphere, which include coupling between physical and dynamical processes, are able to realistically model the observed stationary waves. In a sense, the often posed question – on relative contribution of orography and other processes in forcing of stationary waves – has been addressed by such prognostic general circulation models (GCMs). Comparison of GCM simulations obtained with and without orography provide insight. In these assessments, the change in the heating distribution is attributed to orographic forcing, whose circulation impact is found to be comparable to that of all other processes put together.

Historically, answers to the above question were sought in a framework where ‘orographic forcing’ was used more restrictively – to refer to the dynamical forcing of flow from mechanical diversion. In such analysis, the entire heating distribution, regardless of its origin (e.g., from condensation in adiabatically cooled upslope flow), was regarded as an independent forcing. This framework was adopted, perhaps, because mechanical

diversion of flow by an orographic barrier is conceptually easier to model. Such studies lead to the rapid advancement of stationary wave theory, including construction of potential vorticity conserving models for the responses to orograph, meridional and vertical wave propagation analysis, and understanding of troposphere–stratosphere interaction.

Theoretical Considerations

Large-scale atmospheric motions in the extratropics are approximately hydrostatic and quasi-geostrophic (QG) in character. The hydrostatic approximation recognizes the operative balance between the horizontally varying pressure and density perturbations, while the QG approximation acknowledges the near-balance between the Coriolis force and the horizontal pressure gradient. QG flow is thus dominated by the rotational component. Its evolution, however, is determined, in part, by the comparatively weaker divergent flow component, as described by the vorticity equation

$$\frac{\partial \zeta}{\partial t} + \mathbf{V}_h \cdot \nabla \zeta + \beta v = -(f + \zeta)(\nabla \cdot \mathbf{V}_h) \quad [1]$$

Here, ζ is the QG relative vorticity ($= \hat{k} \cdot (\nabla \times \mathbf{V}_h) = \nabla^2 \psi$), ψ is the geostrophic streamfunction, f is the Coriolis parameter with $\partial f / \partial y = \beta$, and $\mathbf{V}_h$ is the horizontal QG flow. The right-hand term is the product of absolute vorticity ($f + \zeta$) and horizontal convergence, and is often called the ‘stretching term’ because convergent flow leads to stretching of vortex tubes.

Due to compressibility of air, evolution of the thermodynamic state is conveniently described using potential temperature, $\theta = T(p_0/p)^{R/C_p}$, which is conserved in adiabatic motion; p_0 is the reference pressure (1000 hPa). Potential temperature thus changes only in response to diabatic heating $\dot{Q}$, as follows:

$$\frac{\partial \theta}{\partial t} + \mathbf{V}_h \cdot \nabla \theta + w \frac{\partial \theta}{\partial z} = \frac{\dot{Q}}{C_p} (\theta_0/T_0) \quad [2]$$

where $\theta_0 = T_0(p_0/p)^{R/C_p}$, with $T_0 = T(p_0)$.

Since stationary waves refer to the zonally varying component of the flow (here onward denoted by prime), their dynamics can be described, to first order, by linearizing eqns [1] and [2] about the zonal-mean circulation, $\bar{U}(y, z)$ and $\bar{\theta}(y, z)$. The linearized equations are valid for small-amplitude perturbations:

$$\zeta'_t + \bar{U} \zeta'_x + v'(\beta - \bar{U}_{yy}) \approx -f(\nabla \cdot \mathbf{V}'_h) \quad [3]$$

$$\theta'_t + \bar{U} \theta'_x + v' \bar{\theta}_y + w' \bar{\theta}_z \approx (\dot{Q}' \theta_0 / T_0 C_p) \quad [4]$$

For convenience, subscripts are used to denote the partial derivatives.

Orographic Forcing and Response

The forcing and propagation of stationary waves can be discussed using eqns [3] and [4]. In contrast with diabatic heating, which is explicitly present as right-hand forcing in the thermodynamic equation, the mechanical forcing by orography (h') is implicitly present through its kinematic impact on vertical velocity at the lower boundary (w_s). In the presence of the zonal-mean circulation, the linearized vertical velocity, w'_s , equals $\bar{U} h'_x$.

In simplified treatments of orographic interaction, the geophysical fluid is additionally considered to be homogeneous and incompressible ($\nabla \cdot \mathbf{V}_h = -\partial w / \partial z$), so that response is determinable using the vorticity equation alone – this ‘shallow water’ approximation is indeed reasonable for the interaction of oceanic flows with underwater topography, but somewhat limited in capturing aspects of the atmospheric interaction. In shallow water theory, density (or temperature) is constant, and the horizontal flow, including horizontal divergence, is height independent. Assuming that a rigid lid is placed at the top of the fluid ($z = H$), so that vertical velocity vanishes there, one obtains $\partial w' / \partial z \approx -(\bar{U} h'_x) / H$. The forced waves are then modeled by eqn [5], where $\bar{U}$ has been additionally assumed to be latitude independent, and perturbation vorticity is dissipated (e.g., by Ekman spin-down) on an ε^{-1} time scale:

$$[\partial / \partial t + \bar{U} \partial / \partial x + \varepsilon] (\psi'_{xx} + \psi'_{yy}) + \beta \psi'_x \approx -(f/H) \bar{U} h'_x \quad [5]$$

To understand the forced response, consider an arbitrary Fourier component of the geostrophic streamfunction: $\psi'(x, y, t) = \text{Real}\{\hat{\psi}_{k,l} e^{i(kx+ly-\omega t)}\}$, where the hat denotes the complex amplitude corresponding to zonal and meridional wavenumbers, k and l , and associated frequency ω . For such a perturbation, eqn [5] yields the solution

$$\hat{\psi} = \frac{f \hat{h}}{H[(k^2 + l^2)(\bar{U} - c) / \bar{U} - \beta / \bar{U} - i\varepsilon(k^2 + l^2) / (\bar{U} k)]} \quad [6]$$

For stationary waves ($\omega = 0$), the zonal phase speed, $c (= \omega/k)$, vanishes. This simplifies the first term in the denominator to $(k^2 + l^2)$. In the presence of dissipation, the orography and streamfunction are not in phase, since the denominator in eqn [6] is complex. The possibility of resonance is also indicated in the inviscid case ($\varepsilon = 0$), when $(k^2 + l^2) = \beta / \bar{U}$. Dissipation however limits the wave amplitude at resonance, with $\hat{\psi} \propto i \hat{h}$. The streamfunction and orography are 90° phase-shifted (or in quadrature) in this case, with the trough in the flow being a quarter wavelength downstream of the mountain ridge. When forcing is on larger scales, $(k^2 + l^2) < \beta / \bar{U}$, planetary vorticity advection dominates zonal advection of relative vorticity in balancing the orographically induced vorticity on upslopes and downslopes. Both the real and imaginary parts of the denominator in eqn [6] are negative in this case, which puts the trough within a quarter wavelength downstream of the ridge.

It is interesting that troughs in the observed 300 hPa stationary wave pattern (cf. Figure 2(a)) are also downstream of the orographic features, but the extent to which these are forced by local orography remains somewhat uncertain, as discussed later. Also, the assumed Fourier representation of the streamfunction implies the presence of meridional boundaries which confine wave energy to a midlatitude channel – a set-up conducive for resonance. The sinusoidal zonal structure is also unrealistic, since orographic features are generally localized. In nature, the wave energy propagates away zonally, meridionally, and vertically from the localized forcing region, thus calling into question the validity of the solution [6].

The pedagogically useful shallow-water model of orographic interaction is limited for other reasons as well. The tropospheric flow cannot be assumed to be homogeneous and incompressible, since cooling (heating) from adiabatic

expansion (compression) during ascent (descent) is important in the thermodynamic budget. Moreover, a flow configuration which satisfies the vorticity eqn [3] can be unbalanced from the viewpoint of this budget. For example, when planetary vorticity advection dominates the left-hand side in balancing the upslope divergent flow in eqn [3], the thermodynamic budget [4] is unbalanced in the absence of condensation heating (precipitation), since both adiabatic ascent and equatorward flow lead to colder temperatures. The generation of orographic response must thus be understood by considering the vorticity and thermodynamic equations together, so that any implications that one may have for the other are fully accounted for. Such considerations lead to the development of the QG potential vorticity equation.

QG Potential Vorticity Equation

The prediction equation for QG flow that does not explicitly reference the divergent flow component is called the QG potential vorticity equation. Although it can be derived quite generally, the focus here is on its simplified linearized version, when the zonal-mean flow $\bar{U}$ is independent of latitude. The equation is derived by eliminating the divergent flow from eqns [3] and [4]. In the $z^* = (RT_0/g) \ln(p_0/p)$ coordinate, which reduces to geometric height in an isothermal atmosphere, the QG potential vorticity equation is

$$q'_t + \bar{U}q'_x + v'\bar{q}_y = \frac{R}{Hc_p\rho_0} \frac{\partial}{\partial z^*} \left(\frac{\rho_0 \dot{Q}'}{N^2} \right) \quad [7]$$

where

$$q'(x, y, z) = \psi'_{xx} + \psi'_{yy} + \frac{f^2}{N^2\rho_0} \frac{\partial}{\partial z^*} \left(\rho_0 \frac{\partial \psi'}{\partial z^*} \right)$$

and

$$\bar{q}_y(z) = \beta - \frac{f^2}{N^2\rho_0} \frac{\partial}{\partial z^*} \left(\rho_0 \frac{\partial \bar{U}}{\partial z^*} \right) \quad [8]$$

Since divergent flow is not referenced by this equation, it is of some interest to examine the manifestation of orographic forcing in this analysis framework. Not surprisingly, this forcing enters as a lower boundary condition, but in the thermodynamic equation [4]. This is because of the direct reference to vertical velocity in eqn [4], in contrast with the vorticity equation [3] which refers only to its vertical gradient. With $w'_s = \bar{U}h'_x$, the boundary condition conveying orographic forcing is

$$\begin{aligned} \theta'_t + \bar{U}\theta'_x + v'\bar{\theta}_y \\ = -\bar{U}h'_x\bar{\theta}_z + (\dot{Q}'\theta_0/T_0c_p) \text{ at the surface} \end{aligned} \quad [9]$$

Assume for purposes of this discussion that diabatic heating vanishes at the surface, so that only adiabatic cooling (warming) is occurring on the upslope (downslope). In steady flows, the heating can be balanced by zonal eddy advection and/or meridional advection of mean temperature. If upslope cooling is compensated by the latter, the upslope flow will be poleward, and a high-pressure center will be positioned over the mountain ridge near the surface. The response at upper levels depends upon the zonal scale of mountains: large wavelengths will propagate into the lower stratosphere, and phase lines will tilt westward with increasing height, all as depicted in the

(Figure 10(a) schematic. It is interesting that although thermal advection and vertical wave propagation are absent in the shallow water model, the horizontal structure of the long-wavelength solution (in the presence of damping, eqn [6] is not too different from that indicated at upper levels in Figure 10(a).

Heating Response

The stationary wave response to heating can be qualitatively understood from the thermodynamic equation [4]. In the deep tropics, horizontal variations of geopotential (and temperature) are much smaller since it is difficult to maintain them in the presence of the weak Coriolis force. Consequently, horizontal temperature advection is ineffective in balancing diabatic heating in eqn [4]. Away from the surface, heating is

Figure 10 Schematic depiction of the longitude–height response forced by (a) westerly flow over midlatitude orography, (b) tropical heating, and (c) midlatitude heating, all taken from Hoskins and Karoly (1981). The orographic response is shown for the long-wavelength case, and is determined from both dynamic and thermodynamic (i.e., quasi-geostrophic potential vorticity) considerations. The arrows depict vertical motion, and circled crosses and dots denote poleward and equatorward flow, respectively. H and L denote the pressure ridge and trough, with the lines showing the vertical tilt of the pressure wave. W and C are the warmest and coldest air, respectively.

thus balanced, almost entirely, by adiabatic cooling, with the vertical profile of w' closely following that of heating. A substantial portion of heating in the tropics results from deep convection, which produces strongest heating in the mid-to-upper troposphere, as shown later in Figure 11(c). Such heating distribution leads to convergence (divergence) in the lower (upper) troposphere, which results in vortex stretching (squashing). The rotational response to the induced vorticity depends on the horizontal forcing scale: if the scale is large, the stretching is offset by poleward advection of planetary vorticity, which is tantamount to the surface low being positioned westward of the heat source, as schematically illustrated in Figure 10(b).

In the midlatitudes, heating does not extend as deeply into the troposphere as in the tropics. Heating in the Pacific and Atlantic stormtracks, for example, is confined mostly to the lower troposphere, as shown later in Figure 11(b). Midlatitude heating is offset to a large extent by horizontal temperature advection; larger temperature gradients are sustainable in midlatitudes due to the greater Coriolis force. Large-scale heating in midlatitudes is balanced, mostly, by cold advection from the north; the near-surface low is thus positioned eastward of the heating. Interestingly, vertical motion in the vicinity of midlatitude heating is determined by vorticity balance considerations – a complete reversal of the tropical

situation: cold advection from the north brings with it higher vorticity air as well, and this induced vorticity advection must be offset if a steady state is to be maintained. The compensation is accomplished by vortex compression, which has implications for the temperature field.

Wave Propagation

The qualitative arguments discussed above are helpful in understanding the nature of response in the forcing region. The stationary wave response is however not confined to the forcing region alone, since Rossby waves propagate zonally, meridionally, and vertically, carrying the disturbance (energy) into the far field (unforced region). The energy propagation, or group velocity, characteristics depend both on the perturbation scale and structure of the basic state. Some zonal-mean zonal wind configurations encourage Rossby wave propagation, while others impede it. Basic state flow can thus profoundly impact wave propagation into the tropics and the stratosphere.

Theoretical analysis helps to focus on the basic state attributes that are influential, e.g., the direction and curvature of the zonal-mean zonal wind. A useful quantity in wave propagation analysis is the refractive index which seizes on these and other relevant attributes. A display of refractive index variations is often helpful, since it conveys, to first order, the wave

Figure 11 (a) Mass-weighted vertical average of diabatic heating, calculated as a residual from the thermodynamic equation. The winter season (DJFM) diagnosis is obtained from NCEP reanalysis fields 20 winter seasons (1979/80–1998/99). The contour interval is 0.5 K day^{-1} , with dark (light) shading for positive (negative) values in excess of 0.5 K day^{-1} , and zero contours suppressed. (b, c) Zonal-vertical (1000–100 hPa) cross-section of diabatic heating at (b) 37.5° N and (c) 5° N , with contours and shading as in panel (a). The latitudes of the cross-sections in (b) and (c) are marked with thick lines at the edges of panel (a). A 9-point smoother is applied to the heating field before plotting.

propagation pathways, as waves are generally refracted towards higher refractive index regions. Such analysis suggests that midlatitude stationary waves are refracted towards the Equator, drawn there by the large index values resulting from diminishing westerly winds. The tropical easterlies, in contrast, present an effective dynamical barrier to equatorward propagation of midlatitude stationary waves. In the vertical, waves with large horizontal scales alone can propagate upward, but only when the upper-level westerlies are not too strong.

Diabatic Heating in Northern Winter

Diabatic heating plays a prominent role in the forcing of stationary waves. In stationary wave theory, it is an explicit forcing in the QG potential vorticity equation [7], and even orographic forcing in this theoretical framework manifests as surface heating [9].

In nature, heating resulting from the change of phase of water substance, turbulent eddy diffusion, and short-wave and long-wave radiative fluxes is referred to as diabatic heating. (Note that the temperature of air parcels can change even without any diabatic heating, from adiabatic compression or expansion.) In contrast with Earth's orography, whose highly accurate measurements are widely known, the three-dimensional structure of diabatic heating is only beginning to be described. The main reason why the heating distribution has remained uncertain is that, unlike other quantities, heating is not directly measured. It is, instead, estimated, usually as a residual in the thermodynamic budget. Since the heating estimate is only as good as the quality of atmospheric data from which it is diagnosed, the quality of atmospheric analysis is critical for the diagnosis. Fortunately, data coverage and quality and analysis methods have all improved in the last two decades, and are reflected in the modern reanalysis data sets. Heating diagnosis from one such data set, the US National Centers for Environmental Prediction (NCEP) reanalysis, is shown in **Figure 11**.

The mass-weighted vertical average of diabatic heating,

$$\frac{1}{(p_s - 100)} \int_{100}^{p_s} \dot{Q} c_p^{-1} dp$$

is shown during northern winter in units of K day^{-1} ; here, p_s is the surface pressure, c_p is the specific heat of air at constant pressure, and the integration is from the surface to 100 hPa. Key features in **Figure 10(a)** include the heating centers in the extratropical Pacific and Atlantic basins, which effectively define the two midlatitude stormtracks. The northern continents, in contrast, constitute the cooling regions. In the tropics, heating is strong over the South Pacific convergence zone and the Amazon basin. A narrow zone of heating is also present in the Pacific just northward of the Equator; this intertropical convergence zone (ITCZ) is much stronger during northern summer when it is positioned a few degrees farther northward and fully extended across the Pacific basin.

Diabatic heating has a complicated vertical structure which changes with latitude and season. The changes with latitude are shown in **Figure 10(b)** and (c), which depict height–longitude cross-sections through the midlatitude stormtracks (37.5° N

and the ITCZ (5° N). The stormtrack heating is evidently strongest near the surface, with peak values close to 6 K day^{-1} , and diminishes rapidly with height. Latent heating due to precipitation in baroclinically unstable synoptic-scale disturbances is the primary contributor to stormtrack heating. Diabatic cooling, on the other hand, is comparatively weaker, and focused more near the tropopause in this estimation, for reasons that are not clear.

The vertical structure of ITCZ heating is strikingly different. Although the entire column is being heated, heating is generally strongest in the mid-to-upper troposphere. For example, over the tropical Pacific warm pool – the site of persistent deep convection – heating is strongest ($\sim 3 \text{ K day}^{-1}$) at 400 hPa. In contrast, heating over land (e.g., equatorial Africa) is strongest near the surface due to sensible heating. The heating structure over Central America is also similar, except that elevated surface heating there has produced some deep convection as well.

Interaction with Transients

The climatological stationary waves coexist with vigorous atmospheric motions occurring on a variety of time scales (**Figure 9**), and there are strong interactions between these transient motions and the stationary waves. Transient motions are the instantaneous departures of the flow from its climatological state, and the time mean of transient motion thus vanishes, by definition. However, fluxes of heat and vorticity by transients do not vanish in general. For example, the contribution of transients to the advection terms in eqn [2] can be written as

$$\begin{aligned} V''_h \cdot \nabla \theta'' + w'' \partial \theta'' / \partial z \\ \approx \nabla \cdot (V''_h \theta'') + \partial (\omega'' \theta'') / \partial p \end{aligned} \quad [10]$$

where the double prime denotes the transient component and ω is the vertical velocity in p -coordinates. The right-hand side of eqn [10] is the heat-flux divergence from transient motions. In synoptic systems, northward (southward) transient motions are typically accompanied by positive (negative) temperature fluctuations, so that heat flux diverges to the south of a storm-track and converges to the north. The heat-flux divergence acts as heat sources and sinks for the time-mean flow, and the stationary waves respond to this thermal forcing just as they respond to diabatic heating. Likewise, the convergence of transient vorticity flux ($-\nabla \cdot (V''_h \zeta'') - \partial (\omega'' \zeta'') / \partial p$) provides sources and sinks of vorticity for the stationary waves.

The net effect of transient thermal and vorticity fluxes on stationary waves is not easy to characterize. However, it is clear that transient forcing is strong enough in northern winter to exert a powerful influence on stationary waves. The 700 hPa heat-flux convergence by perturbations lasting less than 1 month is superimposed in **Figure 12(a)** on the local winter eddy temperature pattern. The two fields evidently oppose each other. For example, transient heat fluxes diverge from the warmer regions over the Atlantic and the west coast of North America and converge in the colder regions above northeastern Canada. Thus, throughout most of the northern midlatitudes, transient thermal fluxes have a damping effect on the lower tropospheric stationary eddy temperature pattern. Furthermore, the forcing by transient thermal fluxes is on the

Figure 12 (a) The 700 hPa eddy temperature (thick contours) and heat-flux convergence by transient motions (shading and white contours) in northern winter months (DJFM). The contour interval for temperature is 2 K, and dashed lines represent negative values. The contour interval for heat-flux convergence is 0.5 K day⁻¹, with dark (light) shading for positive (negative) values in excess of 0.5 K day⁻¹. Zero contours for temperature and heat-flux convergence are suppressed, and regions where the surface pressure is less than 700 hPa are masked out. (b) Eady growth parameter in northern winter (DJFM), calculated from the 700 hPa temperature gradients. The contour interval is 0.1 day⁻¹, with dark shading for values in excess of 0.6 day⁻¹.

order of 0.5 K day⁻¹, while the eddy temperatures are about 4 K. In the absence of other processes, it would take little more than a week for the thermal fluxes to reduce dramatically the 700 hPa eddy temperature field. Such a reduction also implies a substantial weakening of the upper-level geopotential pattern, since temperature is the vertical derivative of geopotential in hydrostatic balance.

While transients are an important influence on stationary waves, the stationary waves can be equally influential for the transients. One way in which stationary waves organize transients is by creating localized regions of strong cyclogenesis. Synoptic systems tend to develop in regions of strong lower tropospheric temperature gradients, and such regions are present off the coasts of Asia and North America in Figure 12(a). The ability of the local temperature gradient to enhance the growth of synoptic systems can be measured by the Eady growth parameter (ϵ):

$$\epsilon = 0.31 \frac{|\nabla T|}{|T(T_0 \partial \ln \theta / g \partial z)|^{1/2}}$$

Its plot in Figure 12(b) shows large values in the same regions where stormtrack heating occurs in Figure 11(a). Comparison of these panels suggests that stationary waves play an important role in determining the locations of stormtracks. In addition to this effect on growth rate, stationary waves can also have a mechanical effect on stormtracks, by changing the steering winds that determine storm paths and by exchanging mechanical energy with the storms.

The Eady growth rate is applicable to synoptic transients, which grow by extracting energy from the thermal gradients (or vertical shear) of the climatological state. Synoptic systems, in fact, account for less than half of the transient forcing in the vorticity and thermodynamic equations for the climatological stationary waves. Furthermore, the slower transients (those with time scales between, say, 10 days and 1 month) are quite distinct from synoptic transients. They do not generally travel along concentrated stormtracks, nor do they typically grow by extracting energy from the climatological temperature gradients. Although these transients are certainly influenced by the climatological stationary waves, the nature of this influence is rather complex and cannot be easily summarized.

Modeling of Northern Winter Stationary Waves

Modeling of orographically forced stationary waves dates back to the seminal paper of Charney and Eliassen in 1949, in which linear shallow water theory was applied to the longitudinal distribution of orography at 45° N. The earlier discussion here, including the development of eqn [5] and its solution [6], largely follows the analysis reported in that paper. Charney and Eliassen found the midlatitude mountains to be rather influential, accounting for almost all of the observed signal in their analysis.

Since that time, diabatic heating due to continent–ocean contrasts, and transient fluxes of heat and momentum have also been advocated as important mechanisms for the generation of stationary waves. In the intervening period, the atmosphere has been more closely observed, both spatially and temporally, and there has been a tremendous increase in computational power for modeling studies. A reassessment of the relative roles of various forcing mechanisms is thus in order. In effect, more complete versions of the dynamical and thermodynamical equations can now be solved globally at high resolution, and verified against the extensive record of upper-air observations that have been compiled since.

It is still advantageous to linearize the system of equations, at least initially, since this allows the influence of individual forcing terms to be examined separately. Of course, the forcing terms can have strong mutual interactions. For example, heating can cause eddy flow which then impinges on mountains, and the subsequent orographically induced uplift can generate convection and lead to further heating. However, linear diagnostic models serve a valuable purpose in assessing the relative importance of the different forcing terms in different regions. They also indicate the degree to which linear perturbation theory applies to stationary waves.

A linear simulation of northern winter stationary waves is presented in Figure 13. The linear model uses $\sigma = p/p_s$ as the vertical coordinate (here p_s is the surface pressure) so that mountains do not intersect the model levels. There are 15 levels in the vertical, ranging from 1000 to 25 hPa, and the horizontal resolution is 7.5° in the zonal direction and about 2.5° in the meridional direction. As in eqns [3] and [4], the model is linearized about the zonal-mean climatological state. The momentum and thermal dissipation in the model is roughly equivalent to a 5-day damping time scale in eqns [3] and [4]. The forcing consists of three-dimensional diabatic heating (Figure 11), orographic height, and transient fluxes of heat and momentum.

The 300 hPa response obtained with all forcings is shown in Figure 13(a), and plotted using the convention used in Figure 2(a), with which it should be compared. The linear model can simulate the ridge over the Atlantic, the low off the east Asian coast, and the trough over Canada. A notable flaw in the simulation is the weakness of the ridge over the Rockies. The solution shows that linear perturbation theory can explain many, though not all, aspects of the observed stationary wave pattern.

The model response when forced separately by diabatic heating, mountains, and transients is shown in panels (b)–(d), respectively; note that contour interval in these three panels is half that in panel (a). All three forcings contribute significantly to the total pattern. The heating response includes jets in the Asian-Pacific and Atlantic sectors. Heating is evidently important in establishing the ridge over the Atlantic and northern Europe, and contributes significantly to the trough over Canada as well.

The response to mountains in panel (c) shows troughs downstream of the Himalayan-Tibetan complex and the Rockies, as suggested by the shallow water solution [6] and also QG potential vorticity considerations (cf. Figure 10(a)), in each case for long wavelengths. Thus, orography contributes to the forcing of the jets as well. The high amplitudes directly over

Figure 13 (a) The 300-hPa height response of a linear stationary wave model forced by heating, mountains, and transient fluxes of heat and momentum. The contour interval is 50 m, with dark (light) shading for positive (negative) values in excess of 50 m. (b–d) Response of the model when forced separately by (b) heating, (c) mountains, and (d) transient fluxes. The contour interval in (b–d) is 25 m.

Greenland and Tibet are a consequence of the linearization of the hydrostatic equation in σ -coordinates. Examination of geopotential heights gives a somewhat misleading impression that waves generated by mountains propagate primarily in the zonal direction. Examination of the modeled streamfunction (a more suitable variable for describing the rotational response in the tropics; not shown), however, reveals considerable equatorward propagation of the forced waves.

The forcing by submonthly transients (panel d) produces a somewhat intricate pattern with no clear relationship to the synoptic stormtracks. Transients are apparently responsible for a large part of the response over eastern Atlantic and northern Europe.

Studies of stationary wave dynamics have traditionally focused on the question of the relative importance of the various forcing terms in generating the observed pattern. Yet recent simulations such as the one in [Figure 13](#) show clearly that the northern winter stationary waves do not constitute a simple linear response to a single form of forcing. Furthermore, linearized equations, such as eqns [3] and [4], neglect the advection of eddy heat and vorticity by the stationary waves themselves, and also the effect of eddy winds impinging on the mountains. These terms play an important role in generating some features of the stationary wave pattern, such as the ridge over the Rockies. Future examinations of stationary wave dynamics will have to assess not only

the relative importance of various forcing terms but their mutual interactions, and the nonlinear interactions of the stationary waves themselves.

Synopsis

The necessary conditions for symmetric and conditional symmetric instability in a frictionless atmosphere are considered on the basis of parcel theory. The relationship between symmetric and conditional symmetric stability, and gravitational and inertial instability is noted. The possible relationship between some mesoscale precipitation bands in extratropical systems and in tropical cyclones, and conditional symmetric instability, is discussed.

Introduction

Symmetric stability is a state of the atmosphere in which an inviscid, dry air parcel displaced from its equilibrium position with respect to some axis along/about which the flow has no variations, i.e., along/about an axis of symmetry, experiences a restoring force that makes it oscillate about its original position. For axially symmetric displacements in a ring about an axially symmetric vortex the wave motions are called *inertial* or *centrifugal* waves. Centrifugal oscillations are like buoyancy waves with the horizontal centrifugal (inertial) force playing the role of buoyancy (gravity).

Similar oscillations can also occur in a statically stable, rotating atmosphere when the thermal-wind shear vector is unidirectional and does not vary along the direction it is oriented. Parcels in the form of a tube are displaced in a vertical plane normal to the thermal-wind vector. In this case the axis of symmetry is the axis along which the thermal wind is directed.

If potential temperature increases with height and the geostrophic absolute vorticity is anticyclonic, the atmosphere is *inertially unstable*; if the potential temperature decreases with height and the geostrophic absolute vorticity is cyclonic, the atmosphere is *gravitationally* (or *statically*) *unstable*. If the geostrophic absolute vorticity is cyclonic and potential temperature increases with height the atmosphere is both *inertially stable* and *gravitationally stable*; however, if infinitesimal displacements in the plane normal to the vertical shear are accompanied by forces that move the air parcel farther away from its equilibrium position, the atmosphere is *symmetrically unstable*. Since the atmosphere is baroclinic, owing to the thermal wind, this instability is a special case of baroclinic instability for a flow in which there is no temperature-gradient component along the axis of symmetry.

When tubes of moist, unsaturated air are lifted in a symmetrically stable atmosphere to a level at which condensation occurs (and water and ice loading are not significant or are neglected) and thence to a level at which the atmosphere is symmetrically unstable with respect to saturated processes (i.e., when vertical trajectories follow surfaces of constant equivalent or wet-bulb potential temperature instead of surfaces of potential temperature), then the atmosphere is in a state of *conditional symmetric instability* (CSI). CSI is analogous to *conditional instability* for air parcels lifted vertically. Since CSI involves forces that are both horizontally and vertically directed, the process by which the instability is released is also referred to as *slantwise convection*. When a layer of moist air that

is initially symmetrically stable is lifted to saturation and the vertical displacement of air itself creates the conditions for slantwise convection, then the process is referred to as *potential symmetric instability* (PSI), which is analogous to potential instability for upright convection. At saturation, CSI and PSI are equivalent.

The importance of CSI is that it is thought to be responsible for the formation of some mesoscale bands of precipitation that are oriented along the thermal wind. Since the thermal wind is oriented along the elongated zone of strong temperature gradient associated with fronts and is quasi-two-dimensional, CSI may be triggered in response to slantwise, ageostrophic, frontal circulations initiated by confluence/diffuence acting on a cross-frontal temperature gradient. It is also thought that CSI may be responsible for eyewall rainbands in some tropical cyclones.

The Parcel Theory of Symmetric Instability in an Inviscid, Dry Atmosphere

The analysis of symmetric stability is simplified by using a parcel approach analogous to that used in the parcel theory of upright convection. Consider a Cartesian coordinate system in which there is a temperature gradient in the y - p plane and that $\partial/\partial x$ of all variables is 0 (this choice of an axis of symmetry is arbitrary; sometimes the y axis is chosen to be the axis of symmetry). For simplicity the dynamics are described for the Northern Hemisphere. Consider the quantity:

$$m = u - fy, \quad [1]$$

where u is the x -component of the wind and f is the Coriolis parameter. In inviscid flow m , the *absolute momentum* or *pseudo-angular momentum* is conserved; it is attributed to an infinitesimal tube of air extending through some point (y, p) infinitely off in both the $+x$ and $-x$ directions.

The inviscid momentum equation in the y direction, with height as the vertical coordinate, is

$$\frac{Dv}{Dt} = -fu - \frac{1}{\rho} \frac{\partial p}{\partial y} = -f(m - m_g), \quad [2]$$

where v is the y -component of the wind, ρ is the density, p is the pressure, D/Dt is the total (material) derivative, and the geostrophic absolute momentum:

$$m_g = u_g - fy, \quad [3]$$

where u_g is the geostrophic component of the wind in the x direction. Therefore the net force in the y direction on a tube is proportional to the difference between the m of the tube, which is conserved, and the m_g of the environment into which the tube is displaced. It is assumed for simplicity that the tube does not mix with its environment. The original value of m of the tube is just its geostrophic value at its equilibrium point in the y - p plane. Therefore there will be a net force in the y direction on the tube if it moves into an environment where m_g is different from that of its equilibrium, starting location. Vertical gradients of m_g are associated with thermal-wind shear in the x direction (i.e., with temperature gradients in the y direction); gradients of m_g in the y direction are associated with geostrophic absolute vorticity.

The inviscid vertical equation of motion is

$$\frac{Dw}{Dt} = \frac{g}{\theta}(\theta' - \theta), \quad [4]$$

where w is the vertical velocity, g is the acceleration of gravity, θ is the potential temperature of the environment, and θ' is the potential temperature of the tube. If the flow is adiabatic and there is no diffusion of heat, θ' is conserved following the motion of the tube. It is assumed that the environment is not disturbed by the tube's motion so that there is no vertical perturbation pressure-gradient force. Therefore there will be a net force in the vertical on the tube if it moves into an environment where θ is different from that of its equilibrium, starting location.

Whether or not there is a restoring force on the tube that brings it back to its equilibrium point about which it undergoes a stable oscillation (symmetric stability) or whether it continues to move in the direction of its displacement (symmetric instability) depends on how the surfaces of m_g and θ are oriented and what the direction of displacement is with respect to the surfaces (Figure 1). Symmetric instability is possible (panel b of Figure 1) if the slope of the θ surfaces is greater than the slope of the m_g surfaces and if the tube is displaced infinitesimally along a plane whose slope is intermediate between that of the θ surfaces and that of the m_g surfaces (i.e., along paths a or c , but not along paths b or d), and if $\partial\theta/\partial z > 0$ and $\partial m_g/\partial y < 0$. If $\partial\theta/\partial z < 0$ (panel (d) of Figure 1) or if $\partial m_g/\partial y > 0$ (panel (e) of Figure 1), then the atmosphere is statically unstable or inertially unstable, respectively, and not symmetrically unstable. Panel (a) in Figure 1 depicts neutral stability and panel (c) in Figure 1 depicts absolute stability.

The thermal-wind relation in terms of potential temperature is to a good approximation:

$$\frac{\partial u_g}{\partial z} = -\frac{g}{f} \frac{1}{\theta} \frac{\partial \theta}{\partial y}. \quad [5]$$

The slope of a surface of constant θ is therefore

$$\left(\frac{dz}{dy}\right)_\theta = \frac{f(\partial u_g/\partial z)}{g(\partial \theta/\partial y)}, \quad [6]$$

and the slope of a surface of constant m_g is

$$\left(\frac{dz}{dy}\right)_{m_g} = \frac{f - \partial u_g/\partial y}{\partial u_g/\partial z}. \quad [7]$$

It follows that the necessary condition for symmetric instability is

$$Ri = \frac{(g/\theta)(\partial\theta/\partial z)}{(\partial u_g/\partial z)^2} < \frac{f}{(\zeta_g + f)}, \quad [8]$$

where Ri is the Richardson number for the geostrophic wind and ζ_g is the geostrophic vorticity, which for symmetric flow ($\partial/\partial x = 0$) is $-\partial u_g/\partial y$. In typical synoptic-scale flow in mid-latitudes the geostrophic vorticity is an order of magnitude smaller than f ; then the necessary condition for symmetric instability is that $Ri < 1$. In the vicinity of fronts where geostrophic vorticity is much larger, Ri must be smaller.

Ertel's potential vorticity for an atmosphere in geostrophic and hydrostatic balance is

$$Z = \frac{Cp}{\rho} f \frac{g}{\theta} \frac{\partial \theta}{\partial z} \left(\frac{\zeta_g + f}{f} - \frac{1}{Ri} \right). \quad [9]$$

It follows from eqn [8] that an equivalent necessary condition for symmetric instability is that Ertel's potential vorticity for the geostrophic wind is negative (anticyclonic in either hemisphere). Since

$$(\zeta_g + f)_\theta = (\zeta_g + f)_z - \frac{f}{Ri}, \quad [10]$$

where $(\zeta_g + f)_\theta$ is the geostrophic absolute vorticity evaluated on an isentropic surface and $(\zeta_g + f)_z = f - \partial u_g/\partial y$ is the geostrophic absolute vorticity evaluated on a surface of constant height, then negative (anticyclonic in either hemisphere) isentropic geostrophic absolute vorticity is also an equivalent necessary condition for symmetric instability. Thus, symmetric instability is favored on the anticyclonic-shear side of jets and jet streaks or near sharply curved ridges of high pressure.

It can also be shown that the necessary condition for symmetric stability is equivalent to the ellipticity condition for the Sawyer–Eliassen equation, which describes the vertical circulation about a front forced by geostrophic confluence/diffuence and differential diabatic heating and whose dynamics are governed by the geostrophic-momentum approximation. Since the Sawyer–Eliassen equation is a second-order, constant-coefficient, partial differential equation, the condition of ellipticity is necessary for it to have unique solutions. Thus, balanced frontal circulations are possible only if the atmosphere is symmetrically stable. However, if friction is included in the equations of motion, it turns out that the ellipticity condition can be met even when Ertel's potential vorticity is negative.

The Parcel Theory of Slantwise Convection in an Inviscid, Moist Atmosphere

The analysis of symmetric instability in a moist atmosphere is complicated by latent heat release, evaporation and melting-related cooling, and by water and ice loading. The governing momentum equation remains as eqn [2]. The governing vertical equation of motion, on the other hand, is different from eqn [4] since it must account for latent heat release, and if there is a condensate, for water and ice loading also. Surfaces of constant entropy that account for latent heat release and for condensate loading replace potential temperature in eqn [4]. If both the environment and the tube are unsaturated and there is

Figure 1 Stability criteria for symmetric flow ($\partial/\partial x = 0$) in terms of the slope of the m_g (solid lines) and potential-temperature θ (dashed lines) surfaces. Displacements in the directions a , b , c , and d are referred to in the text. (a) Neutral stability for displacements along the θ and m_g surfaces; otherwise stable for infinitesimal displacements; (b) symmetric instability: unstable for infinitesimal slantwise displacements intermediate in slope between that of θ surfaces and m_g surfaces; otherwise stable; (c) absolute stability: stable for any infinitesimal slantwise displacement; (d) gravitational instability: unstable for any infinitesimal slantwise displacement not along a θ surface; and (e) inertial instability: unstable for any infinitesimal slantwise displacement not along an m_g surface. Adapted from Bluestein, H.B., 1993. *Synoptic-Dynamic Meteorology in Midlatitudes. Observations and Theory of Weather Systems*, vol. II. By permission of Oxford University Press, New York.

no condensate, then virtual potential temperature (θ_v) may be used in place of potential temperature. If the tube is saturated and the environment is unsaturated, and if condensate is ignored, then potential temperature of the tube may be replaced by equivalent virtual potential temperature (θ_{ev}); if both the tube and the environment are saturated, and if condensate is ignored, then the potential temperature of both the tube and environment may be replaced by equivalent virtual potential temperature. (Wet-bulb virtual potential temperature (θ_{wv}) may be used instead of equivalent virtual potential temperature.)

For the purpose of illustration consider an atmosphere that is unsaturated and has no condensate, but is moist.

Suppose that the distribution of θ_v , θ_{ev} , and m_g is as shown in **Figure 2**. Since the slope of the surfaces of constant θ_v are not steeper than the surfaces of constant m_g at low levels, the atmosphere there is symmetrically stable or even neutral with respect to unsaturated displacements. However, there are regions aloft where the slope of surfaces of constant θ_{ev} is steeper than the surfaces of m_g . In these regions, if condensate loading is ignored, the atmosphere is symmetrically unstable with respect to infinitesimal saturated displacements. Since the stability depends upon whether or not a tube is saturated or unsaturated, the symmetric instability condition is *conditional*.

Figure 2 Idealized example of a vertical cross section in the Northern Hemisphere, normal to the thermal-wind shear vector, showing surfaces of constant m_g (solid lines), and constant θ_v , θ_{ev} , and θ_{wv} . In this example θ_v , θ_{ev} , and θ_{wv} increase with height (gravitational and conditional stability), m_g decreases with increasing y (inertial stability), and θ_v decreases with y (baroclinic atmosphere, with colder air at larger values of y). Lifting condensation level (LCL); level of free slantwise convection (LFS); level of neutral buoyancy (LNB). Below the LCL the slope of the θ_v surface is less than that of the m_g surface. Note that the slope of θ_{ev} and θ_{wv} surfaces is greater than the slope of θ_v surfaces because the lapse rate of a θ_v surface is greater than that of a θ_{ev} or θ_{wv} surface, and θ_v , θ_{ev} , and θ_{wv} decrease with y . Adapted from Bluestein, H.B., 1993. *Synoptic-Dynamic Meteorology in Midlatitudes. Observations and Theory of Weather Systems, vol. II*. By permission of Oxford University Press, New York.

Suppose an unsaturated tube at low levels is lifted a *finite* distance along a surface of constant θ_v (e.g., by the ascending branch of a frontal circulation or more slowly as a result of quasigeostrophic forcing) until it reaches its lifting condensation level and that condensate is ignored: If lifted any further, it follows a surface of constant θ_{ev} . Thus far the tube is neutrally buoyant. Owing to the inclusion of the effects of latent heat, the surfaces of constant θ_{ev} have different slopes than that of the surfaces of constant θ_v . The m of the tube is greater than that in its environment everywhere to the right of the original m_g surface; therefore according to eqn [2] the tube is symmetrically stable because it feels a restoring force that has a component to the left; if the tube were not forced any further, it would become negatively buoyant and move back down and to the left toward its original equilibrium position. The tube is symmetrically stable even though it is saturated and the slope of the surfaces of constant θ_{ev} is greater than the slope of the surfaces of constant m_g because the tube has undergone a finite displacement rather than an infinitesimal displacement.

If the tube is lifted further, however, so that eventually it crosses to the left of the original m_g surface, and it is displaced upward and to the right at a slope intermediate between that of the θ_{ev} and m_g surfaces, then according to eqns [4] and [2] it would continue to accelerate upward and to the right if it were not forced any more. The level at which it would first realize symmetric instability is called the *level of free slantwise convection*, in analogy with the level of free convection for upright convection.

Eventually the tube will reach a level at which it crosses back to the right side of the original m_g surface where the slope of the θ_{ev} surfaces is now less than that of the m_g surfaces. Above this level, the *level of neutral buoyancy* (LNB) for slantwise convection, the atmosphere is symmetrically stable. The LNB tends to be near the tropopause where θ surfaces are more horizontally oriented owing to the strong static stability [6] in the lower stratosphere and where m_g surfaces are more vertically oriented owing to the lack of horizontal temperature gradient and thermal-wind shear [7] at the tropopause.

The amount of kinetic energy it takes to lift a tube to its level of free slantwise is called the *slantwise convective inhibition* (SCIN). The potential energy in the environment that is converted into kinetic energy of the tube while it is symmetrically unstable is called the *slantwise convective available potential energy* (SCAPE). SCIN and SCAPE are the analogs to the convective inhibition and convective available potential energy (CAPE) in the parcel theory of upright convection. The SCAPE is equivalent to CAPE computed along a surface of constant m_g . In the geostrophic coordinate system used in semigeostrophic theory, m_g surfaces are parallel to the geostrophic coordinate, which is directed opposite in direction to the horizontal temperature gradient. Thus SCAPE is CAPE computed in geostrophic coordinates. In the limit of vanishing baroclinicity, m_g surfaces become vertically oriented (see eqn [7] when $\partial u_g / \partial z \rightarrow 0$) and SCAPE is identical to CAPE.

If the atmosphere is saturated, then an equivalent necessary condition for CSI is that Ertel's potential vorticity for saturated moist processes is negative (anticyclonic in either hemisphere). If the effects of condensate are accounted for, the criteria for CSI are more complicated. The loading depends on what phase of water substance is present; condensate that falls out does not follow air parcel motion and may evaporate into unsaturated air.

In order for precipitation bands to form as a result of slantwise moist convection, there must be an adequate supply of water vapor, strong enough lift to release CSI, and the necessary conditions for CSI must be satisfied.

The slantwise ascent of symmetrically unstable tubes must be compensated for by slantwise-descending air. The regions of slantwise-descending air modify the environment so as to make the tubes less symmetrically unstable, just as compensating subsidence around buoyant clouds (according to the *slice method* in the theory of upright convection) warms the environment and lessens the buoyancy in the clouds (i.e., the CAPE is diminished). The narrower the slantwise-ascending branch and the wider the slantwise-descending branch, the less is the slantwise acceleration (i.e., the less is the SCAPE). The most unstable configuration is one of thin, relatively rapidly slantwise-ascending layers of saturated air sandwiched in between thick, less-rapidly slantwise-descending layers of unsaturated air that are being cooled evaporatively from precipitation falling out from above. If the most unstable configuration is the one most likely to occur, then CSI precipitation bands should be relatively narrow and widely spaced.

The horizontal scale of CSI precipitation bands estimated from the horizontal extent of a sloping m_g surface [7] is U_g/f , where U_g is the change in geostrophic wind in the layer of CSI. For typical values of U_g in midlatitudes, the horizontal scale of CSI precipitation bands is on the order of 100 km, which is mesoscale.

Observations of Conditional Symmetric Instability and Precipitation Bands

Slantwise convection may be triggered suddenly after a gradual buildup in SCAPE by synoptic-scale or mesoscale processes, or it may be in statistical equilibrium so that the SCAPE is nearly zero and constant. Since the latter is the frequently observed case, it is not easy to use SCAPE as a forecast tool because its absence does not preclude the possibility that CSI is in fact being released; the existing observational network cannot resolve the space and time scales of the production of CSI and its release when the atmosphere is in statistical equilibrium.

Bands of precipitation ahead of warm fronts may be due to CSI. The bands are important in that large amounts of precipitation may accumulate in mesoscale regions, which makes the forecasting of floods and heavy snow difficult; synoptic-scale dynamics, on the other hand, can only explain how lower amounts of precipitation accumulate over broader regions. The slanted convection in the eyewall of some rapidly intensifying tropical cyclones might also be a result of CSI. In this case, the temperature gradient is directed toward the center of the tropical cyclone.

While lightning activity is common when conditional instability is released, it is thought it can also occur when CSI is released, even though updrafts in slantwise convection are usually much weaker. Lightning is commonly observed in the trailing precipitation region of mesoscale convective systems and sometimes in wintertime convection and in the eyewall of deepening tropical cyclones, where the likelihood of conditional instability is small, but there can be CSI.

When Ertel's potential vorticity for moist processes is very small, i.e., when the atmosphere is nearly neutral with respect to CSI, the atmosphere's response to frontogenetical forcing is enhanced. Since frontal secondary circulations and the secondary circulations in tropical cyclones themselves can produce precipitation bands, it is therefore not always easy to distinguish between bands forced by the secondary circulations and the bands forced by CSI.

The state of the atmosphere sometimes evolves so that the necessary conditions for gravitational, inertial, and symmetric instability/CSI appear and disappear. When small-scale

gravitational instability weakens and is followed by mesoscale, symmetric instability, there is said to be 'upscale development.' There is some evidence that the trailing, 'stratiform' precipitation region in some mesoscale convective systems may represent upscale development, as air ascends at the leading convective line in an environment of conditional instability, and then leans over into a trailing region of CSI.

When mesoscale frontal ascent in a symmetrically unstable atmosphere leads to latent heat release and is followed by small-scale, elevated gravitational instability, there is said to be 'downscale development.' In any event, it has been argued that there is a continuum between the gravitational and symmetric instabilities, so that a distinction between the two is somewhat arbitrary.

Introduction

The spin of a solid body is characterized by the angular velocity about its axis of rotation. This angular velocity is related in a simple manner to the spin angular momentum, which is conserved in the absence of torques, thus providing a powerful constraint on the motion. Owing to the fact that, unlike a solid body, a fluid provides little resistance to shearing deformation, angular velocity as defined for a solid body is not a suitable measure of rotation in a fluid. In the presence of velocity shear, straight-line flow can have strong local rotation, while curved flow may have zero local rotation (Figure 1). Vorticity is a vector field which, by providing a local measure of the instantaneous rotation of a fluid parcel, plays a role in fluid dynamics analogous to angular velocity in solid body

Figure 1 Behavior of a paddle wheel spinning about a vertical axis under two types of horizontal flow: (a) linear jet with positive and negative shear vorticity and (b) curved flow with zero net vorticity. Reproduced from Holton, J.R., 1992. *An Introduction to Dynamic Meteorology*, third ed. Academic Press, Orlando, FL.

mechanics. A related quantity called potential vorticity (*see Dynamical Meteorology: Overview*) is a fluid analog to the spin angular momentum of a solid body.

In most meteorological systems, horizontal wind velocities greatly exceed the vertical velocity, and the vertical component of vorticity (which depends on the horizontal velocity field) is of primary interest. Vorticity has the property that it is advected by the winds, but at the same time influences the wind distribution. Temporal and spatial variations of vorticity play key roles in the diagnosis of the development and evolution of weather systems, and of the general circulation of the atmosphere.

The Nature of Vorticity

Vorticity, ω , is defined as the curl of the fluid velocity. It is thus a vector field, and has a direction and amplitude at every point in space. Lines parallel to the vorticity field are referred to as vortex lines, while the volume defined by all of the vortex lines passing through a closed loop is referred to as a vortex tube. In meteorology, it is necessary to distinguish between the absolute vorticity ω_a , which is the curl of the absolute velocity observed in a coordinate frame fixed in space ($\mathbf{U}_a$), and the relative vorticity ω , which is the curl of the relative velocity observed in a coordinate system rotating with the Earth ($\mathbf{U}$, the wind velocity):

$$\omega_a \equiv \nabla \times \mathbf{U}_a, \quad \omega \equiv \nabla \times \mathbf{U} \quad [1]$$

In Cartesian coordinates rotating with the Earth, with x, y , and z directed eastward, northward, and upward, respectively, and with the velocity components designated by $\mathbf{U} = (u, v, w)$, the components of vorticity are

$$\omega = \left(\frac{\partial w}{\partial y} - \frac{\partial v}{\partial z}, \frac{\partial u}{\partial z} - \frac{\partial w}{\partial x}, \frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} \right) \quad [2]$$

Large-scale dynamic meteorology is concerned with the vertical components of absolute and relative vorticity, which are designated by η and ζ , respectively:

$$\eta \equiv \mathbf{k} \cdot (\nabla \times \mathbf{U}_a), \quad \zeta \equiv \mathbf{k} \cdot (\nabla \times \mathbf{U})$$

That vorticity is the natural measure of local fluid rotation that can be demonstrated by considering the special case of horizontal motion with no z dependence: $\mathbf{U} = (u, v)$. In that case, the relative vorticity has only a vertical component:

$$\zeta = \frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} \quad [3]$$

Figure 2 shows two short line segments, radiating from point A at (x_0, y_0) of lengths δx and δy , which are perpendicular to each other at time $t = 0$. The velocity at point A is (u_0, v_0) .

Figure 2 Relation of vorticity in two-dimensional flow to the instantaneous rotation of two orthogonal line segments.

The velocity normal to the line AB at the point $x_0 + \delta x$ is $v_0 + (\partial v / \partial x) \delta x$, while the velocity normal to the line AC at the point $y_0 + \delta y$ is $u_0 + (\partial u / \partial y) \delta y$. The instantaneous counterclockwise angular velocity of line AB is thus $[(v_0 + (\partial v / \partial x) \delta x) - v_0] / \delta x = \partial v / \partial x$, while for line AC the instantaneous counterclockwise angular velocity is $[-(u_0 + (\partial u / \partial y) \delta y) + u_0] / \delta y = -\partial u / \partial y$. The average of the angular velocity in the two orthogonal directions is thus $\zeta / 2 = \frac{1}{2}(\partial v / \partial x - \partial u / \partial y)$, that is, one-half of the vorticity.

The difference between absolute and relative vorticity is the planetary vorticity, which is just the local vertical component of the vorticity of the Earth owing to its rotation; $2\Omega \sin \phi \equiv f$, where ϕ is the latitude, and f is referred to as the Coriolis parameter. Thus, $\eta = \zeta + f$, or, in Cartesian coordinates,

$$\zeta = \frac{\partial v}{\partial x} - \frac{\partial u}{\partial y}, \quad \eta = \frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} + f$$

The Relation between Vorticity, Circulation, and Potential Vorticity

Vorticity is related to another quantity, referred to as the fluid circulation. Circulation, which is a scalar integral quantity, is a macroscopic measure of rotation for a finite area. Vorticity, on the other hand, is a vector field that gives a microscopic measure of the rotation at every point in the fluid.

The circulation, C , is defined as the line integral about the contour, $\mathbf{l}$, of the component of the velocity vector that is locally tangent to the contour (Figure 3):

$$C \equiv \oint \mathbf{U} \cdot d\mathbf{l} \quad [4]$$

By convention, the circulation is evaluated by counterclockwise integration around the contour. Thus, $C > 0$ corresponds to a cyclonic circulation in the Northern Hemisphere. According to Kelvin's circulation theorem, the absolute

Figure 3 Circulation about an arbitrary closed contour.

circulation (computed using the velocity with respect to coordinates fixed in space) is conserved following the fluid motion for loops of fluid parcels on isobaric or isentropic surfaces. This conservation law is somewhat analogous to conservation of angular momentum in solid body mechanics.

Circulation is related to vorticity via Stokes's theorem, which states that

$$C \equiv \oint \mathbf{U} \cdot d\mathbf{l} = \iint_A (\nabla \times \mathbf{U}) \cdot \mathbf{n} dA \quad [5]$$

where A is the area enclosed by the contour, and the unit normal $\mathbf{n}$ is defined by the counterclockwise sense of the line integration using the right-hand thumb rule. Equation [5] shows that the vertical components of absolute and relative vorticity are related to the absolute and relative circulations by

$$\eta = \lim_{\delta A \rightarrow 0} \frac{C_a}{\delta A}, \quad \zeta = \lim_{\delta A \rightarrow 0} \frac{C}{\delta A} \quad [6]$$

where C_a and C are the absolute and relative circulations, respectively, given by line integrals over closed loops in the horizontal plane.

For an infinitesimal parcel of air, the Kelvin circulation theorem and eqn [6] imply that

$$\eta \delta A = (\zeta + f) \delta A = \text{Const} \quad [7]$$

If the atmosphere is approximated as a barotropic layer of depth h , in which horizontal velocity is independent of height and the density is assumed to be constant then eqn [7] leads to a simple and powerful conservation law. The arbitrary area in eqn [7] can be eliminated by observing that the mass of a column of fluid of depth h , cross-sectional area δA , and density ρ is $M = \rho h \delta A$. Since mass is conserved, this relation can be combined with eqn [7] to show that

$$\left(\frac{\eta}{h} \right) = \left(\frac{(\zeta + f)}{h} \right) = \text{Const} \quad [8]$$

Thus, following the horizontal motion of a cylinder of fluid, an increase in depth h must lead to a corresponding increase in the absolute vorticity. If latitude remains constant this implies an increase in relative vorticity. On the other hand, a decrease in depth h requires a reduction in the absolute vorticity. The conserved quantity in eqn [8] is referred to as the barotropic potential vorticity. This relation shows clearly how vertical stretching concentrates vorticity, while vertical shrinking dilutes vorticity.

Vorticity Equation

Equation [8] states that the barotropic potential vorticity of a fluid cylinder is conserved following the motion. This implies that

$$\frac{D_h}{Dt} \left(\frac{\zeta + f}{h} \right) = 0 \quad [9]$$

where the derivative is taken following the fluid motion.

If the flow is purely horizontal ($w = 0$), as must be the case for a homogeneous incompressible fluid of constant depth then eqn [9] can be simplified to obtain the barotropic vorticity equation

$$\frac{D_h(\zeta + f)}{Dt} = 0 \quad [10]$$

which states that absolute vorticity is conserved following the horizontal motion. More generally, absolute vorticity is conserved for any fluid layer in which the divergence of the horizontal wind vanishes, without the requirement that the flow be barotropic. For horizontal motion that is nondivergent ($\partial u/\partial x + \partial v/\partial y = 0$), the flow field can be completely represented by a stream function $\psi(x, y)$ defined so that lines of constant C are parallel to the velocity vector at every point, and the velocity $\mathbf{V} = \mathbf{k} \times \nabla\psi$ is proportional to the gradient of ψ . The velocity components are thus given by $u = -\partial\psi/\partial y$, $v = \partial\psi/\partial x$, and the vorticity is $\zeta = \partial v/\partial x - \partial u/\partial y = \partial^2\psi/\partial x^2 + \partial^2\psi/\partial y^2 \equiv \nabla^2\psi$. Thus, the velocity field and the vorticity can both be represented in terms of the variation of the single scalar field $\psi(x, y)$, and the barotropic vorticity equation can be written as a prognostic equation for vorticity in the form

$$\frac{\partial}{\partial t} \nabla^2\psi = -\mathbf{V} \cdot \nabla(\nabla^2\psi + f) \quad [11]$$

where $\mathbf{V} = \mathbf{k} \times \nabla\psi$ is the nondivergent horizontal wind. This equation states that the local tendency of relative vorticity is given by the advection of absolute vorticity. Equation [11] can be solved numerically to predict the evolution of the stream function, and hence of the vorticity and wind fields. Since the flow in the mid-troposphere is often nearly nondivergent on the synoptic scale, eqn [11] provides a surprisingly good model for short-term forecasts of the synoptic scale 500 hPa flow field.

Vorticity Patterns in the Atmosphere

Regions of positive ζ tend to develop in association with cyclonic storms in the Northern Hemisphere and on the poleward sides of westerly jet streams, while regions of negative ζ are associated with anticyclones and the equatorward side of westerly jet streams. (The signs are reversed in the Southern Hemisphere.) Thus, the distribution of relative vorticity is an excellent diagnostic for weather analysis. As discussed in the previous section, absolute vorticity tends to be conserved following the motion at mid-tropospheric levels; this conservation property is the basis for the simplest dynamical forecast scheme given by eqn [11].

The relationship between relative vorticity and the relative circulation C discussed above, and the roles of flow curvature and shear in contributing to vorticity can be clearly seen by

Figure 4 Circulation for an infinitesimal loop bounded by two streamlines and two lines orthogonal to the wind direction. Reproduced from Holton, J.R., 1992. *An Introduction to Dynamic Meteorology*, third ed. Academic Press, Orlando, FL.

considering the circulation about the closed contour shown in Figure 4. If the circulation is computed for the infinitesimal contour shown in Figure 4 (noting that there is no contribution along the line segments AC and BD, because these are perpendicular to the velocity), the result is

$$\delta C = V[\delta s + d(\delta s)] - \left(V + \frac{\partial V}{\partial n} \delta n \right) \delta s$$

But from Figure 4, it is seen that $d(\delta s) = \delta\beta \delta n$, where $\delta\beta$ is the angular change in the wind direction in the distance δs . Hence,

$$\delta C = \left(-\frac{\partial V}{\partial n} + V \frac{\delta\beta}{\delta s} \right) \delta n \delta s$$

or in the limit $\delta n, \delta s \rightarrow 0$

$$\zeta = \lim_{\delta n, \delta s \rightarrow 0} \frac{\delta C}{(\delta n \delta s)} = -\frac{\partial V}{\partial n} + \frac{V}{R_s} \quad [12]$$

where $R_s = (\delta\beta/\delta s)^{-1}$ is the radius of curvature of the streamlines. The net vertical vorticity component is thus the result of the sum of two parts: (1) the rate of change of wind speed normal to the direction of flow $-\partial V/\partial n$, called the shear vorticity; and (2) the turning of the wind along a streamline V/R_s , called the curvature vorticity. The contributions of shear and curvature vorticity to the pattern of vorticity on the 500 hPa isobaric surface in the atmosphere can be seen in the vorticity map of Figure 5.

Integral Constraints on Vorticity

When the influence of the divergence and convergence associated with the large-scale vertical motion is taken into account, the vorticity equation can be rewritten as

$$\frac{\partial \zeta}{\partial t} = -\nabla \cdot [(\zeta + f)\mathbf{V}] \quad [13]$$

Equation [13] expresses the remarkable fact that if frictional and diabatic effects are neglected then vorticity can be changed only by the divergence or convergence of the horizontal flux of vorticity given in brackets on the right-hand side. The vorticity cannot be changed by vertical transfer of vorticity across a horizontal surface. Integration of eqn [13] over the globe

Figure 5 Vorticity (color) and geopotential height (solid contours, meters) for the 500 hPa surface in the Eastern North Pacific sector on 4 February 2002. The height contours approximate a stream function for the large-scale flow, so are approximately parallel to the winds, and where the lines are close together the wind is strong. Regions of large absolute vorticity (red) occur in conjunction with troughs in the geopotential height (e.g., over Canada), in closed cyclonic circulations (e.g., over Montana), and along the cyclonic shear side of the jet stream (e.g., the South West (SW) to North East (NE) flow over the Pacific). Negative relative vorticity (light blue) occurs in ridges and on the equatorward side of the jet stream. shows that for a horizontal surface that does not intersect the surface of the Earth the global average of ζ is constant. Furthermore, the integration of ζ over the sphere shows that the global average ζ is exactly zero. Vorticity on such a surface is neither created nor destroyed; it is merely concentrated or diluted by the convergence or divergence of horizontal fluxes. This last result holds even when friction and diabatic effects are included.

Introduction

In 1964, Charney and Eliassen introduced the term CISK (conditional instability of the second kind) to describe a positive feedback between deep moist convection and a large-scale circulation. They hypothesized that hurricane intensification was such a process, in which surface friction helps to induce low-level convergence into a vortex, resulting in deep convection and latent heating that amplify the vortex. In the late 1960s, Yamasaki and Hayashi first considered the feedbacks between deep convection and large-scale equatorial waves. In their models, convection could intensify (destabilize) the wave in some cases through purely inviscid processes not dependent on feedbacks with surface drag or surface thermodynamic fluxes. In 1974, Lindzen termed this destabilization wave-CISK, to distinguish it from Charney and Eliassen's frictional CISK, and put forth perhaps the most expansive view of the role of wave-CISK, implicating it in the development of tropical circulations from squall lines to the Madden-Julian Oscillation.

Wave-CISK has proved a somewhat slippery hypothesis to test, and has largely fallen from favor among specialists in convective dynamics. The predicted instabilities are very sensitive to the representation of cumulus convection. For simple models the fastest-growing instabilities have very short wavelengths, and are not clearly separable from conventional conditional instability of individual cumulus clouds. However, wave-CISK is a mode of instability permitted by many convective parameterizations, including some used in climate models, so it can be a useful concept in interpreting model output even if physically dubious.

The class of convective parameterizations that tend to lead to wave-CISK instabilities are those that diagnose convective mass flux based on column-integrated horizontal moisture convergence. The Arakawa-Schubert scheme, a typical 'quasi-equilibrium' closure in which the convective mass flux is chosen so as to regulate the local convectively available potential energy, does not support wave-CISK, as shown by Stark. Neither does the Betts-Miller scheme, a typical moist adjustment convective parameterization, as shown by Neelin and Yu, although Hayashi and Golder showed that CISK could be excited if the convective adjustment turns on and off frequently. In recent years, moisture-convergence-based convective parameterizations have been criticized for using a nonlocal measure (moisture convergence) to regulate a local thermodynamic process (convection), allowing unrealistic soundings to develop. Furthermore, the development of wave-CISK is strongly influenced by the vertical profile of convective heating perturbation selected by the parameterization. 'Top-heavy' heating perturbations concentrated in the upper troposphere are most favorable for wave-CISK instabilities.

A Simple Wave-CISK Model

In its simplest form, wave-CISK can be phrased in terms of a nonrotating inviscid gravity wave interacting with a simple parameterization of moist convection. Wave-induced perturbations in surface heat flux and radiative fluxes are neglected. Classically, a linear stability analysis of a small-amplitude wave is used to assess the convective feedback.

We consider the mathematical structure of an extremely simple wave-CISK model based on small-amplitude (linear) two-dimensional inviscid hydrostatic motions of a nonrotating atmosphere. The pressure velocity ω is assumed to be zero at the mean surface pressure $p = p_s$. At the tropopause pressure p_t , a similar boundary condition or a boundary condition that allows upward-propagating gravity waves to radiate out of the domain may be applied.

The mean convection is assumed to maintain the same profile of water vapor mixing ratio $q(p)$ everywhere. This is a very strong simplifying assumption on the column moisture budget, and one of the weakest links in simple wave-CISK models. In addition, most such models have not explicitly attempted to maintain a consistency between the mean temperature and moisture profiles that ensures that boundary layer air will be conditionally unstable, and hence able to convect, but will not penetrate much above the tropopause. Such consistency requires a basic state in which the moist static energy is similar at the tropopause to that in the boundary layer, which relates the assumed $q(p_s)$ to the assumed troposphere-mean static stability.

The perturbation convective heating in any column is assumed to be caused by the conversion of the converged moisture into rainfall; the resulting latent heating is redistributed through the column by turbulent convection according to a fixed vertical heating profile $\eta(p)$, which is normalized to have a mean value of unity averaged over the depth of the atmosphere. The thermodynamic equation for geopotential perturbation $\phi(x, p, t)$ is eqn [1].

$$\frac{\partial}{\partial t} \frac{\partial \phi}{\partial p} + \sigma \omega = \frac{LR}{pC_p(p_b - p_t)} \eta(p)M \quad [1]$$

In eqn [1], x is the horizontal coordinate, t is time, σ is the static stability parameter, $M(x, t)$ is the perturbation column-integrated horizontal moisture convergence, R and C_p are the gas constant and isobaric specific heat of air, and L is the latent heat of vaporization for water vapor. Using the continuity equation, the moisture convergence can be written as eqn [2].

$$M = \int_{p_t}^{p_s} q(p) \frac{\partial \omega}{\partial p} \frac{dp}{g} \quad [2]$$

Applying the horizontal momentum and continuity equations results in a linear, separable equation for $\omega(x, p, t)$ (eqn [3]).

$$\frac{\partial^2}{\partial t^2} \frac{\partial^2 \omega}{\partial p^2} + \sigma \frac{\partial^2 \omega}{\partial x^2} = \frac{LR}{pC_p(p_b - p_t)} \eta(p) \frac{\partial^2 M}{\partial x^2} \quad [3]$$

With a rigid-lid boundary condition, $\omega(p_s) = \omega(p_t) = 0$. A radiation boundary condition would relate $\omega(p_t)$ to its vertical derivative. In either case, this equation admits normal modes of the form $\omega = \hat{\omega}(p) \exp(ik[x - ct])$. In the case of constant σ , Cho and Pendlebury showed how the complex phase speed c can be calculated by a transcendental equation most easily derived by Fourier-analyzing $\hat{\omega}(p)$ and the normalized heating profile $\eta(p)$. Unstable modes ($\text{Im}(c) > 0$) exist for a variety of heating profiles. Use of a radiation boundary condition instead of a rigid lid at the tropopause usually has a minor effect on the unstable modes.

Raymond has given a simple physical description of wave-CISK by regarding the convective heating as a series of pulses, each of which acts as a vertically distributed source of gravity waves. He then showed that for a wave moving at a particular phase speed, the gravity wave generated by the pulse heating would generate low-level horizontal convergence in phase with the preexisting wave, causing the wave to amplify.

An important feature of the eigenvalue problem is that the horizontal wavenumber k cancels out of the equation. This implies that if an instability is present, shorter wavelengths will grow fastest (no short-wave cutoff), since the growth rate is proportional to $\text{Im}(kc)$. This suggests that wave-CISK might manifest itself at the shortest scale at which the model assumptions are still plausible. Since the model assumes an ensemble convective heating response, this scale would have to be somewhat larger than the spacing between convective clouds or cloud groups. However, on such scales other mechanisms such as cold-pool dynamics seems to play a more important role in organizing convection into mesoscale systems.

The short-wavelength behavior is related to the difficulty of clearly separating wave-CISK in this model from conventional conditional instability of individual cumuli. For a given temperature profile, moistening the near-surface air will render the profile more conditionally unstable to individual cumuli. Our simple CISK model exhibits a distorted version of this same mechanism, rendering dubious the notion of CISK as a distinct instability of cumulus cloud ensembles. To see this, we can integrate eqn [2] by parts as in eqn [4].

$$M = - \int_{p_t}^{p_s} \omega \frac{\partial q}{\partial p} \frac{dp}{g} \quad [4]$$

This expresses the parameterized moisture convergence, and hence the cumulus-induced heating rate, as proportional to the vertical velocity weighted by dq/dp . This heating counteracts the adiabatic cooling associated with rising motion, reducing the effective static stability of the lower and mid-troposphere. If the near-surface air is sufficiently humid, this effective static stability can become negative, promoting short-wavelength CISK instabilities. Within the framework of our CISK model, this condition of negative effective static stability plays the same role as conventional conditional instability does for growth of individual cumuli.

The stability analysis is more involved for convective parameterizations that do not employ a moisture convergence closure, and only a few such studies have been published. The complication is that the right-hand side of eqn [3], which

involves the horizontal Laplacian of the heating, is not usually expressible purely in terms of ω . Although a similar eigenvalue problem for c can often still be formulated, it usually must be solved numerically by vertical discretization and may now have a short-wave cutoff.

Elaborations on the Basic Model

Many elaborations on the above model have been proposed. In 1970, Hayashi extended a similar model to continuously stratified motions on an equatorial beta-plane using separation of variables in the meridional direction. In particular, the equatorial Kelvin wave has a similar zonal structure and growth rate to a nonrotating gravity wave. This has led to many theories that rationalize the tropical Madden-Julian (intraseasonal) oscillation as a wave-CISK mode. More sophisticated general circulation model simulations using moisture-convergence-based convective parameterizations, starting with Hayashi and Sumi in 1986, have also frequently produced intraseasonal oscillations that have been interpreted as wave-CISK.

In 1979, Davies obtained a short-wavelength cutoff by assuming a short delay between the moisture convergence and the convection. With a 30–60-minute delay, the fastest growing wavelength is a few hundred kilometers, corresponding to a typical size of a mesoscale convective system. In 1987, Lau and Peng considered ‘positive-only heating’, in which only upward motion (creating moisture convergence) produces perturbation heat release. This can be thought of as a simple way to represent waves sufficiently strong to suppress all convection in their subsiding branches, but still weak enough to be approximated by linear dynamics. Such models produce unstable modes with a propagating narrow band of ascent surrounded by a broad subsidence region. This could be considered as a parameterized representation of the circulation around a single intense cumulonimbus.

Additional physical feedbacks have been considered. In 1990 Wang and Rui considered frictional wave-CISK, the impact of surface friction and convective heating on an equatorial wave, and found that the surface drag could stimulate a pattern of convective heating that helps destabilize an equatorial Kelvin wave. Mak considered the feedback of cumulus convection (represented via eqn [2]) with an Eady model of mid-latitude baroclinic instability. He showed that the most unstable Eady mode becomes shorter and intensifies more rapidly when moderate cumulus-driven latent heating is included; these effects can be interpreted in part as consequences of a reduced effective static stability. With sufficiently strong cumulus heating, his theory also predicted new classes of boundary-trapped CISK modes. Emanuel found a baroclinic wave-CISK mode varying perpendicularly to the wind shear, somewhat akin to symmetric instability, which can be excited in a broader set of conditions than classical wave-CISK modes. These theories await decisive testing against observations and more sophisticated numerical models.

Current Status of Wave-CISK

Neither observations nor current cloud-resolving numerical model simulations clearly show classical wave-CISK-like

modes. Furthermore, the theoretical models that predict wave-CISK are based on dubious parameterizations of cumulus convection. However, there are many intriguing indications that moist convection may in fact help destabilize some large-scale waves through mechanisms not considered in classical wave-CISK. Some of these include: (i) the effect of wave-associated surface wind perturbations on the surface fluxes and boundary layer structure (wind-induced surface heat exchange, or WISHE); (ii) radiative feedbacks on the wave associated with convectively produced anvils or moisture redistribution; and (iii) feedbacks between the convection and the humidity profile in the convecting column. The importance of these convective/large-scale feedbacks in producing transient variability in the tropics and parts of the mid-latitudes on all time scales remains an active and very important topic of research.

Introduction

The complexity of atmospheric flow encourages the use of simplified conceptual models to study specific processes. A conceptual model is here interpreted as a model that includes a broad range of physical features but is still sufficiently simple to permit a complete description of its properties. The theory of wave mean-flow interaction encompasses a family of such conceptual models. The flows considered generally have nontrivial dependence on all three spatial coordinates and also on time.

Some degree of simplification is achieved by assuming that the flow can be split into a wave and a mean component, such that the mean has large amplitude and is slowly evolving, while the wave has smaller amplitude and may evolve on a faster time scale and a shorter length scale.

The theory is based on the assumption the mean flow depends only on a reduced number of coordinates. It is further assumed that the mean-flow variation with respect to one of the remaining coordinates is weak. The mean could be taken over time or space, but the discussion below will concentrate on an example for which a spatial mean is used and the system has multiple scales of variation in time.

Superimposed on the mean flow is a wave field. The waves depend on all four coordinates but are often assumed to have small amplitude.

The concept of multiple scales is important here. Atmospheric dynamics is often analysed by assuming that every component of the flow varies according to the same set of representative scales. In the theory of wave mean-flow interaction that assumption is relaxed slightly by allowing different scales for different components of the flow. The two components are a mean flow and a wave field. These interact through the nonlinearity of the governing equations. The time scale for the evolution of the mean flow is much longer than that which characterizes the wave propagation. In many applications there is also a faster time characterizing the period of individual waves.

Zonal Averaging and Multiple Time Scales

The theory of wave mean-flow interaction can be applied to a wide range of flows. Here the general principles will be illustrated through a discussion of a single example, described later. This section introduces the relevant equations and averaging procedure. The complete set of equations for this problem consists of the thermodynamic equation, the horizontal momentum equations, mass conservation, and the hydrostatic equation. The hydrostatic approximation has the effect of reducing the system from five to three predictive equations by filtering out sound waves. This approximation is valid when the typical velocities of the flow are small compared

to the phase speed of sound waves. These equations may be written as [1], [2], [3], [4] and [5].

$$\text{Thermodynamic} \quad \theta_t + u\theta_x + v\theta_y + w\theta_z = Q \quad [1]$$

$$\begin{aligned} \text{x - Momentum} \\ u_t + uu_x + vv_y + ww_z - fv = \Phi_x + F \end{aligned} \quad [2]$$

$$\begin{aligned} \text{y - Momentum} \\ v_t + uv_x + vv_y + ww_z + fu = \Phi_y + G \end{aligned} \quad [3]$$

$$\text{Mass} \quad u_x + v_y + \rho_s^{-1}(w\rho_s)_z = 0 \quad [4]$$

$$\text{Hydrostatic} \quad \theta = \frac{\theta_{\text{ref}}}{g} \Phi_z \quad [5]$$

In these equations, z is the log pressure vertical coordinate (see **Dynamical Meteorology: Overview**) and $\rho_s(Z) = \rho_s(0) \exp(-z/H)$ is the corresponding pseudodensity (H is a reference scale height). (u, v, w) are the three components of the wind, θ is potential temperature, and Φ is the geopotential height. Q represents diabatic heating and F and G represent diffusion terms. In numerical or conceptual models F and G can also include the effects of small-scale turbulent mixing that is not explicitly represented.

We now introduce a small parameter ε that will represent the amplitude of the waves. The associated changes to the mean flow will occur on a time scale proportional to ε^{-2} . To represent this mathematically, we introduce a fast time $\tau = t$ and a slow time $T = \varepsilon^{-2}t$. The variables u, v, w, θ , and Φ are then all expanded in powers of ε as follows in eqn [6a].

$$\begin{aligned} u(x, y, z, t) = & u^{(0)}(y, z, T) \\ & + \varepsilon u^{(1)}(x, y, z, \tau, T) \\ & + \varepsilon^2 u^{(2)}(x, y, z, \tau, T) + \dots \end{aligned} \quad [6a]$$

Note that the leading-order term is independent both of the zonal coordinate x and of the fast time τ . It follows from the definition of the fast and slow times that temporal derivatives can be expanded as in eqn [6b].

$$\frac{\partial}{\partial t} = \frac{\partial}{\partial \tau} + \varepsilon^2 \frac{\partial}{\partial T} \quad [6b]$$

With the introduction of two time variables to replace a single one, the problem is rendered underspecified. That is, we have increased the number of variables that need to be determined without having a corresponding increase in the number of equations we can use to determine these variables. This property will be turned to advantage later on, when it is used to impose conditions that facilitate the clean separation of different parts of the problem along physically meaningful lines.

The leading order equations are [7], [8], [9], [10] and [11].

$$v^{(0)}\theta_y^{(0)} + w^{(0)}\theta_z^{(0)} = Q^{(0)} \quad [7]$$

$$v^{(0)} \left[u_y^{(0)} - f \right] + w^{(0)} u_z^{(0)} = F^{(0)} \quad [8]$$

$$v^{(0)} v_y^{(0)} + w^{(0)} v_z^{(0)} + f u^{(0)} = \Phi_y^{(0)} + G^{(0)} \quad [9]$$

$$v_y^{(0)} + \rho_s^{-1} \left(w^{(0)} \rho_s \right)_z = 0 \quad [10]$$

$$\theta^{(0)} = \frac{\theta_{\text{ref}}}{g} \Phi_z^{(0)} \quad [11]$$

It will be assumed that the leading-order solution is unforced, so that $Q^{(0)}$, $F^{(0)}$, and $G^{(0)}$ all vanish. The first and second equations imply, in general, $v^{(0)}, w^{(0)} = 0$. Equation [10] is then satisfied automatically. The remaining two equations then show that the zonal flow is in hydrostatic and geostrophic balance. These two can be combined to form the thermal wind eqn [12].

$$\theta_y^{(0)} = g^{-1} \theta_{\text{ref}} f u_z^{(0)} \quad [12]$$

The wave equations, at order ε , are [13], [14], [15], [16] and [17].

$$\theta_t^{(1)} + u^{(0)} \theta_x^{(0)} + v^{(1)} \theta_y^{(0)} + w^{(1)} \theta_z^{(0)} = Q^{(1)} \quad [13]$$

$$u_t^{(1)} + u^{(0)} u_x^{(0)} + v^{(1)} u_y^{(0)} + w^{(1)} u_z^{(0)} - f v^{(1)} = \Phi_x^{(1)} + F^{(1)} \quad [14]$$

$$v_t^{(1)} + u^{(0)} v_x^{(1)} + f u^{(1)} = \Phi_y^{(1)} + G^{(1)} \quad [15]$$

$$u_x^{(1)} + v_y^{(1)} + \frac{1}{\rho_s} \left(w^{(1)} \rho_s \right)_z = 0 \quad [16]$$

$$\theta^{(1)} = \frac{\theta_{\text{ref}}}{g} \Phi_z^{(1)} \quad [17]$$

These five equations describe a wide variety of wave propagation mechanisms, including gravity waves, Rossby waves, inertial waves, Kelvin waves and mixed Rossby gravity waves.

The equations are invariant with respect to the x coordinate and it is known that the underlying physics can be expressed in a Hamiltonian formulation. For Hamiltonian systems there is a general theorem, due to Emmy Noether, stating that there is an invariant related to every symmetry. The invariant that is associated with the x -symmetry of the underlying physics is momentum. The momentum-like invariant that is associated with the x -symmetry of the perturbation equations is known as the pseudomomentum and takes the form shown in eqn [18a].

$$A = -\rho_s \frac{\overline{u_z^{(1)} \theta^{(1)}}}{\overline{\theta_z^{(0)}}} + \left(\frac{\rho_s}{\overline{\theta_z^{(0)}}} \right)^2 \left(\frac{\overline{u_z^{(0)}}}{\rho_s} \right) \frac{\overline{\theta^{(1)^2}}}{2} + \frac{1}{2} \left(\frac{\rho_s}{\overline{\theta_z^{(0)}}} \right)^2 \frac{\overline{(q^{(1)} \theta_z^{(0)} - \theta^{(1)} q_z^{(0)})}}{q_y^{(0)} \theta_z^{(0)} - \theta_y^{(0)} q_z^{(0)}} \quad [18a]$$

In eqn [18], q is Ertel's potential vorticity, given by eqn [18b].

$$q = \frac{(f + v_x - u_y) \theta_z + u_z \theta_y - v_z \theta_x}{\rho_s} \quad [18b]$$

The bracketed group in the numerator of the last term on the right-hand side of [18a] is related to the isentropic anomaly of q . The isentropic anomaly is of greater dynamical significance than the isobaric anomaly $q^{(1)}$ because q is materially conserved on isentropes in adiabatic, inviscid flow. A is also known as the 'wave activity'.

The expression for wave activity [18a] is complicated, but this complexity is compensated for by a relatively simple evolution equation (eqn [19], where $\nabla = (\partial/\partial y, \partial/\partial z)$).

$$A_t + \nabla \cdot \mathbf{F}^{\text{ep}} = D. \quad [19]$$

The right-hand side, D , is a dissipative term depending linearly on $Q^{(1)}$, $F^{(1)}$, and $G^{(1)}$. The conservative wave dynamics are described by the Eliassen-Palm flux vector $\mathbf{F}^{\text{ep}}$ whose components are given by eqns [20] and [21].

$$F_y^{\text{ep}} = \rho_s \left(\overline{-u^{(1)} v^{(1)}} + \frac{\overline{\theta^{(1)} v^{(1)}}}{\overline{\theta_z^{(0)}}} u_z^{(0)} \right) \quad [20]$$

$$F_z^{\text{ep}} = -\rho_s \left(\overline{u^{(1)} w^{(1)}} + \frac{\overline{\theta^{(1)} v^{(1)}}}{\overline{\theta_z^{(0)}}} \left[u_y^{(0)} - f \right] \right) \quad [21]$$

The evolution equation for the wave activity [19] follows from the linear wave equations [13], [14], [15], [16] and [17] without any further approximation. The unwieldy definition of A is compensated for by the simple structure of the evolution equation. While it is easy enough to verify that A has the properties listed, it would not be easy to find such a quantity without the guidance that comes from Noether's theorem. The existence of such an exact form is important in guaranteeing the validity of the approximations made to the wave equations below. This would not be a problem if we were only concerned with a local approximation, but the problem here requires an approximation to be valid over many vertical wavelengths and many wave periods.

A further useful property of the wave action is that, under circumstances in which a group velocity c_g is well defined, the flux of wave activity is given by $F^{\text{ep}} = c_g A$.

Mean-Flow Evolution

The equation for the slow evolution of the mean flow is obtained from the order ε^2 terms in the expansion of the governing equations. The zonal-mean zonal-momentum and thermodynamic equations take following forms [22] and [23].

$$u_T^{(0)} - \overline{v^{(2)}} \left[f - u_y^{(0)} \right] + \overline{w^{(2)}} u_z^{(0)} = - \left(\overline{u^{(1)} v^{(1)}} \right)_y - \rho_s^{-1} \left(\rho_s \overline{u^{(1)} w^{(1)}} \right)_z \quad [22]$$

$$\theta_T^{(0)} + \overline{v^{(2)}} \theta_y^{(0)} + \overline{w^{(2)}} \theta_z^{(0)} = - \left(\overline{\theta^{(1)} v^{(1)}} \right)_y - \rho_s^{-1} \left(\rho_s \overline{\theta^{(1)} w^{(1)}} \right)_z + \overline{Q^{(2)}} \quad [23]$$

It was mentioned earlier that the introduction of two time variables made the problem underspecified. The associated freedom has been used here to impose the conditions $\overline{u^{(2)}} = 0$ and $\overline{\theta^{(2)}} = 0$, so that all changes in the mean zonal flow and

potential temperature are included in the leading-order terms $\overline{u^{(0)}}$ and $\overline{\theta^{(0)}}$. Equations [22] and [23] show that the mean flow is forced by the convergence of the Reynolds' stress and the mean potential temperature is changed by the convergence of the heat flux. The system can respond to forcing through two physically distinct mechanisms: the tendency (represented by $u_T^{(0)}$ and $\theta_T^{(0)}$) and the mean meridional circulation (represented by $\overline{v^{(2)}}$, $\overline{w^{(2)}}$).

The analysis in the previous section showed that the eddy fluxes that occur in [22] and [23] as forcings of the mean flow also occur in [20] and [21] representing the flux of wave activity. A transformation to what are known as the transformed Eulerian mean equations clarifies the link between mean-flow forcing and the wave propagation. The aim of the transformation is to reorganize the equations so that all the forcing terms can be collected into a single expression. This achieved by defining the residual circulation as in eqns [24] and [25].

$$\overline{v^*} = \overline{v^{(2)}} - \frac{1}{\rho_s} \frac{\partial}{\partial z} \left(\frac{\rho_s \overline{v^{(1)} \theta^{(1)}}}{\theta_z^{(0)}} \right) \quad [24]$$

$$\overline{w^*} = \overline{w^{(2)}} + \frac{\partial}{\partial y} \left(\frac{\overline{v^{(1)} \theta^{(1)}}}{\theta_z^{(0)}} \right) \quad [25]$$

Modified means are defined for the potential temperature [26] and heating rate [27].

$$\overline{\theta^*} = \overline{\theta^{(0)}} + \varepsilon^2 \frac{\partial}{\partial z} \left(\frac{\overline{\theta^{(1)2}}}{\theta_z^{(0)}} \right) \quad [26]$$

$$\overline{Q^*} = \overline{Q^{(2)}} + \frac{\partial}{\partial z} \left(\frac{\overline{\theta^{(1)} Q^{(1)}}}{\theta_z^{(0)}} \right) \quad [27]$$

The resulting transformed Eulerian mean equations are [28a] and [28b] where terms that are fourth-order in wave amplitude have been neglected. The transformed Eulerian mean equations [28] gain

$$u_T^{(0)} - \overline{v^*} [f - u_y^{(0)}] + \overline{w^*} u_z^{(0)} = \nabla \cdot \mathbf{F}^{\text{ep}} \quad [28a]$$

$$\overline{\theta_T^*} + \overline{v^*} \overline{\theta_y^*} + \overline{w^*} \overline{\theta_z^*} = \overline{Q^*} \quad [28b]$$

their significance not only from the fact that the eddy forcing terms have been collected into a single term but also from the fact that this single term, $\nabla \cdot \mathbf{F}^{\text{ep}}$, is the same as the term describing the evolution of the pseudomomentum in [19]. There is thus a clear link between the wave forcing of the mean flow and the wave propagation. The solutions of eqns [28a] and [28b] are constrained by the thermal wind equations [12] for the zonal flow and by mass conservation in the residual circulation. This in turn means that the eddy forcing and the thermal forcings ($\nabla \cdot \mathbf{F}^{\text{ep}}$ and $\overline{Q^*}$ respectively) cannot, in general, be independently specified. When considering wave-driven circulations, the thermal term may be considered as a relaxation term, pulling the atmosphere back toward a thermal equilibrium on a time scale T_Q , say. In other contexts

it may make more sense to consider the thermal term as forcing, rather than responding.

The system still has two modes of response: zonal acceleration or meridional circulation. The relative magnitude of these two modes can be analyzed by eliminating the meridional circulation from [28a] and [28b] using the equation of mass conservation ($\overline{v_y^*} + \rho_s^{-1} (\rho_s \overline{w^*})_z = 0$), and expressing the tendencies in terms of a potential ($u_T^{(0)}, \theta_T^{(0)} = (\chi_y, -\theta_{\text{ref}} f g^{-1} \chi_z)$) (which is possible because of the thermal wind equation). An elliptical equation for χ can then be derived. Analysis of this equation reveals that the nature of the response depends on the nondimensional parameter $C_F = C_T / (1+B-1)$, where $C_T = T_F / T_Q$ is the ratio of times scales. (T_F is the time scale of the forcing) and $B = L_F^2 f^2 / (H_F^2 N^2)$ is the Burgers number (N is the Brunt-Väisälä frequency; L_F, H_F are the horizontal and vertical length scales of the eddy forcing). If C_F is large, the response will tend to be in the meridional circulation; when C_F is small, the response will be mainly in the zonal acceleration. Small C_F may result from either a small ratio of time scales or a small Burger number. If, for example, we take parameter values representative of large-scale seasonally varying forcing ($L_F = 10^6$ m, $H_F = 8 \times 10^3$ m, $T_F = 8 \times 10^6$ s, $T_Q = 8 \times 10^5$ s, and $N^2 = 4 \times 10^{-4}$ s⁻¹) then taking a tropical value of the Coriolis parameter ($f = 10^{-5}$ s⁻¹) gives $C_F \approx 0.04$, whereas taking a mid-latitude value ($f = 10^{-4}$ s⁻¹) gives $C_F \approx 4$.

Thus, for eddy forcing on seasonal times scale the mid-latitude response should be dominated by the meridional circulation, whereas the tropical response will be dominated by zonal accelerations. The next section analyses the latter scenario in more detail.

The Quasi-Biennial Oscillation

As the title 'wave mean-flow interaction' implies, it is important not only to understand how the waves modify the mean flow but also to quantify how the mean flow affects the waves. The latter component of the interaction is illustrated beautifully by the cyclic variation in the zonal winds of the tropical stratosphere known as the quasi-biennial oscillation (QBO; see **Middle Atmosphere: Quasi-Biennial Oscillation**).

The QBO is a wave-forced oscillation with an irregular period slightly longer than 2 years. The atmospheric phenomenon is described in more detail in a separate article. The QBO is forced by a variety of different waves. Here the focus will be on a simple conceptual model forced by a single class of waves that are thought to play an important role. To further simplify the exposition, the meridional structure will be neglected and the Coriolis parameter will be taken as zero. These simplifications eliminate the Rossby, Rossby-gravity, inertial, and Kelvin waves from the system, leaving only gravity waves.

In this case there is a very good separation of scales. The mean flow varies with a period of slightly over 2 years, whereas the time scale for the propagation of waves through the stratosphere is a matter of hours or days, depending on the type of waves in question.

Since the wave equations include a z -dependent coefficient, $u^{(0)}$, they do not have simple sinusoidal solutions. However, if the vertical scale of the variation is large compared to the

vertical wavelength of the waves, this variation can be neglected to leading order. This approximation can be made rigorous using the Liouville–Green method, but a detailed analysis of the approximations made will be omitted here to preserve the focus on wave mean-flow interaction. To deal with this rigorously, it is necessary to introduce a scale separation between the wavelength of the eddies and the length scale of variations in the mean flow.

If the vertical variation of $u^{(0)}$ is neglected these equations have solutions of the form [29], where $\gamma = 1/(2H)$ and $[\tilde{\theta}, \tilde{u}, \tilde{w}, \tilde{\Phi}]$ are complex constants.

$$\begin{aligned} [\theta^{(1)}, u^{(1)}, w^{(1)}, \Phi^{(1)}] &= \text{Re}\{[\tilde{\theta}, \tilde{u}, \tilde{w}, \tilde{\Phi}] \\ &\times \exp(i(kx + mz - \omega t) + \gamma z)\} \end{aligned} \quad [29]$$

If [29] is substituted into the linear eqns [13], [14], [15], [16] and [17], it is found that these constants must satisfy the matrix equation [30].

$$\begin{pmatrix} i(\omega - u^{(0)}k) & 0 & \theta_z^{(0)} & 0 \\ 0 & i(\omega - u^{(0)}k) & 0 & -ik \\ 0 & ik & im - \gamma & 0 \\ 1 & 0 & 0 & (im + \gamma)\theta_0 g^{-1} \end{pmatrix} \begin{pmatrix} \tilde{\theta} \\ \tilde{u} \\ \tilde{w} \\ \tilde{\Phi} \end{pmatrix} = 0 \quad [30]$$

Equation [30] only has nonzero solutions if the determinant of the matrix vanishes. This condition leads to the dispersion relation [31] relating the frequency ω to the wave vector (k, m) .

$$\omega = ku^{(0)} \pm \frac{kN}{\sqrt{m^2 + \gamma^2}} \quad [31]$$

The corresponding group velocity is given by eqn [32].

$$c_{gz} = \frac{\partial \omega}{\partial m} = \frac{kmN}{(m^2 + \gamma^2)^{3/2}} \quad [32]$$

If such a plane wave propagates into a region of different $u^{(0)}$, then [31] must continue to be fulfilled. The frequency and zonal wavenumber are fixed by the boundary conditions, so the only means that the wave has of maintaining [31] is by adjusting the vertical wavenumber m . Rearranging [31] gives eqn [33].

$$m^2 = \left(\frac{N}{c - u^{(0)}} \right)^2 - \gamma^2 \quad [33]$$

As $c - u^{(0)}$ decreases, m^2 must increase. This will have two effects: The speed of vertical propagation will decrease and the rate at which the wave is dissipated by thermal damping will increase.

With the neglect of the meridional structure, the wave activity eqns [18a], [19], [20] and [21] are greatly simplified:

$$A_t - \left(\overline{\rho_s w^{(1)} u^{(1)}} \right)_z = D \quad [34]$$

Equation [34] shows that steady ($A_t = 0$) conservative ($D = 0$) waves have vanishing Reynolds stress. In other words,

there is no wave mean-flow interaction. Nonconservative processes could include radiation and nonlinear processes associated with wave breaking. In keeping with the policy of taking the simplest representation necessary to illustrate wave mean-flow interaction, these nonconservative processes will be represented by a simple linear damping on the wave activity.

The wave field is most easily represented as a superposition of weakly interacting waves, each identified by a wavenumber and frequency. The orthogonality of the different waves then implies that the Reynolds stress and the wave activity can both be expressed as the sum of the contributions from individual waves. Let $\tilde{A}(k, \omega; z)$ be the wave activity associated with wavenumber k and frequency ω , and suppose that the corresponding linear damping rate is $\alpha(k, \omega)$. For steady conditions (that is, with no variation on the short time scale) and neglecting order ε^4 term associated with slow time scale variations, the wave activity equation becomes [35].

$$\frac{\partial}{\partial z} \left[\overline{\rho_s w^{(1)} u^{(1)}} \right] = \sum_{k, \omega} \alpha \tilde{A}(k, \omega; z) \quad [35]$$

As mentioned above, the z dependence of A is assumed to take place on a scale much larger than the vertical wavelength.

With $u_z^{(0)} = 0$ and $q^{(0)} = q^{(1)} = 0$, the contribution to the pseudomomentum from a single wave component is given by eqn [36], where the $\dagger$ indicates a complex conjugate.

$$\tilde{A}(k, \omega; z) = -\text{Re}[(im + \gamma)\tilde{u}\tilde{\theta}^\dagger] \frac{\rho_s}{\theta_z^{(0)}} \quad [36]$$

The Reynolds stress can also be expressed as a sum of different wavenumber and frequency contributions, and it can be shown that eqn [37] holds.

$$\begin{aligned} \overline{w^{(1)} u^{(1)}} \rho_s &= \sum_{k, \omega} \text{Re}[\tilde{u}\tilde{w}^\dagger] \rho_s \\ &= -\sum_{k, \omega} c_{gz} \tilde{A}(k, \omega; z) \end{aligned} \quad [37]$$

Hence, given the independence of the propagation of different wave components, eqn [35] becomes eqn [38].

$$\frac{\partial}{\partial z} [c_{gz} \tilde{A}(k, \omega; z)] = -\alpha \tilde{A}(k, \omega; z) \quad [38]$$

Integrating with respect to z gives the vertical structure of the wave activity (eqn [39]).

$$\begin{aligned} \tilde{A}(k, \omega; z) &= \frac{c_{gz}(0) \tilde{A}(k, \omega; 0)}{c_{gz}(z)} \\ &\times \exp\left(-\int_0^z \frac{\alpha}{c_{gz}(z')} dz'\right) \end{aligned} \quad [39]$$

The corresponding slow variation in the mean flow is given by eqn [40].

$$\rho_s u_T^{(0)} = -\sum_{k, \omega} \alpha \tilde{A}(k, \omega; z) \quad [40]$$

In general, the dissipation rate α will depend both on the wavenumber and the amplitude of the waves. Figure 1 shows sketches of five different types of behavior, depending both on the ratio of the dissipation time scale to the vertical propagation time scale and on the type of dissipation. In I and II the dissipation rate is constant. The key factor then is whether the

Figure 1 Different paradigms of dissipating vertically propagating waves. I, overdispersed; II, underdispersed; III, critical level; IV, continuous breaking; and V, catastrophic breaking.

growth of the wave due to the density effect dominates over the dissipation. For $2\alpha H > c_{gz}$ the wave decays with height (I), otherwise it grows (II). Another possibility is that the wave encounters a critical line (where the phase speed matches the mean zonal wind, $u^{(0)}$). In this case α is peaked near the critical line and there is no propagation above the critical line (III). Finally, the growth in amplitude with height can lead to wave breaking. This can either be continuous, where the value of α is such as to keep the amplitude constant with height (IV), or catastrophic, in which episodes of wave breaking drastically reduce the wave amplitude (V).

In the equatorial stratosphere, Rossby-gravity waves generally fit into category I, while Kelvin waves and gravity waves are more likely to be in III–V.

In order to focus on wave mean-flow interaction, the simplest form of dissipation will be assumed here: $\alpha = \text{constant}$. It will further be assumed that the criticality parameter $2\alpha H c_{gz}^{-1}$ is close to unity, so that the wave amplitude does not vary greatly throughout the domain. This situation lies between cases I and II in Figure 1.

Figure 2 shows the acceleration that will result from an initially sinusoidal vertical structure in $u^{(0)}$ (the heavy solid line) when the wave field consists of two vertically propagating waves with equal and opposite zonal phase speeds, $c = \pm c_0$. The dot-dashed lines show how the wave activity would decay with height in the absence of any mean flow. The thin solid lines show the actual decay with height. There is a relative enhancement of the $c > 0$ wave in the region $u^{(0)} > 0$ and of the $c < 0$ wave in the region $u^{(0)} < 0$. Taking the sum of these, and rescaling, gives the heavy dashed line. The forcing of the mean flow is proportional to this line. There is a clear tendency to accelerate the mean flow and also to displace the flow downward.

Summary

The theory of wave mean-flow interaction rests on a division of the flow into a large-amplitude, slowly evolving mean and a small-amplitude, rapidly evolving wave. Despite their small amplitude, the waves are able to force significant changes to the

Figure 2 Idealized forcing generated by gravity waves propagating through a sinusoidally varying basic state (see discussion in text).

mean flow on the longer time scale relevant for mean-flow evolution. The time scale separation was used to derive one set of equations describing the wave propagation and another set describing the mean flow changes forced by the waves.

The pseudomomentum is introduced to describe the wave evolution over time and space scales much greater than the typical wave scales. The pseudomomentum gives a phase-independent measure of the wave amplitude without introducing any approximations. This allows subtle effects arising

from the slight, mean flow-induced, variations in wave propagation and absorption properties to be described accurately and concisely.

It was then shown how a transformation of the mean flow evolution equations allows the eddy forcing terms they contain to be related to the evolution of the pseudomomentum.

The way in which the mean-flow modification by the waves and the modulation of wave propagation by the mean flow can feedback on each other was illustrated with a simple model of the quasi-biennial oscillation, forced by gravity waves.

The amplification of zonal flow anomalies due to gravity wave forcing can arise because a positive zonal flow anomaly slows down the vertical propagation of those gravity waves with a positive phase velocity. The slower vertical propagation leads to a stronger interaction within a given height range. In the case of gravity waves, this interaction tends to drive the zonal flow toward the gravity wave phase speed. The end result is that the positive flow anomaly will be reinforced through a stronger interaction with gravity waves having a positive phase velocity.

The downward propagation of the zonal flow anomalies depends on the details of the selective wave absorption. If there is strong absorption, the amplitude of the positive phase speed waves will decrease with height through the region of positive winds. This means that a given flow anomaly will be reinforced more strongly below its maximum than above. The displacement of the forcing relative to the anomaly causes the anomaly to drift downward. The fact that waves of a positive phase velocity are being preferentially absorbed in a positive flow anomaly means that higher up there will be a deficit relative to the negative phase velocity waves. This implies that there will be a net negative forcing at higher levels, tending to generate negative flow anomalies above positive ones.

The negative anomalies will then drift downward, so that a repeating pattern of alternating and descending mean flow anomalies is generated.

Wave mean-flow interaction is important in many other areas of atmospheric dynamics, such as sudden warmings in the winter polar stratosphere, in the maintenance of the jet streams in the extratropical upper troposphere, and in the formation of blocks at the end of the mid-latitude storm tracks. The theory makes it possible to analyze these complex flows in terms of the propagation of small-amplitude waves and their feedback on the mean flow. The wave activity formalism allows the wave propagation to be described in terms of the group velocity and provides a direct link between that propagation and induced changes in the mean flow.

Introduction

Waves in the atmosphere are oscillatory motions that result from a balance between the inertia of the atmosphere and a restoring force. Atmospheric waves are important because they can transmit energy and momentum without material transport of air parcels. Most weather disturbances are associated with one or more types of atmospheric wave. Owing to wave propagation, disturbances in one region can influence the weather in a remote region on time scales much shorter than the transit time for air parcels. In order to predict the weather or to simulate the climate it is necessary to properly account for the influence of wave propagation. Examples of important atmospheric waves are buoyancy waves, inertia-gravity waves, and Rossby waves. In buoyancy waves the vertical stability of the atmosphere acts as a restoring force; in inertia-gravity waves the Coriolis force and buoyancy force both act as restoring forces; and in Rossby waves a fluid analog of spin angular momentum (potential vorticity) acts as the restoring force.

Phase Velocity and Group Velocity

The simplest atmospheric waves are sinusoidal oscillations that satisfy linearized forms of the dynamical equations. The dynamical equations are linearized by assuming that all dependent field variables can be divided into two parts, a basic state portion, which is usually assumed to be an east–west flow independent of time and longitude, and a disturbance portion, which represents an oscillatory deviation of the field from its basic state and is assumed to be sufficiently small so that terms quadratic in the disturbance variables can be neglected. Thus, for example, if $\bar{u}$ designates a time- and longitude-averaged zonal velocity, u' is the deviation from that average, and x and t designate the zonal coordinate and time, respectively, then the complete zonal velocity field is $u(x, t) = \bar{u} + u'(x, t)$ and the inertial acceleration $u\partial u/\partial x$ can be written as eqn [1].

$$u \frac{\partial u}{\partial x} = (\bar{u} + u') \frac{\partial}{\partial x} (\bar{u} + u') \approx \bar{u} \frac{\partial u'}{\partial x} \quad [1]$$

When the dynamical equations are linearized in this fashion, and the basic state flow is sufficiently simple, it is often possible to find analytic solutions in the form of sinusoidal waves. For example, a sinusoidal wave propagating in the zonal direction can be represented by eqn [2], where $|C|$ is the amplitude and ϕ , the argument of the complex exponential, is the phase.

$$f(x, t) = \text{Re}[C \exp(i\phi)] \quad [2]$$

In a propagating wave, phase depends on time and space. Thus, for a one-dimensional wave propagating in the x

direction, the wave phase can be represented by $\phi(x, t) = kx - \nu t$. Here the wave number, k , is defined as 2π divided by the wavelength, L_x , and frequency, ν , is 2π divided by the wave period. For zonally propagating waves, the phase is constant for an observer moving at the zonal phase speed $c_x = \nu/k$. This may be verified by observing that if phase is to remain constant following the motion, eqn [3] must be satisfied.

$$\frac{D\phi}{Dt} = \frac{D}{Dt} (kx - \nu t) = k \frac{Dx}{Dt} - \nu = 0 \quad [3]$$

where D/Dt designates differentiation following the motion. Thus, $(Dx/Dt)\phi=\text{const} = c_x = \nu/k$. By convention it is assumed that $k > 0$; then for $\nu > 0$, $c_x > 0$, so that phase propagates in the positive direction, while for $\nu < 0$ phase propagates in the negative direction.

In some waves (for example, acoustic waves) parcel oscillations are parallel to the direction of phase propagation. However, most meteorologically important waves are transverse waves in which the parcel oscillations are perpendicular to the direction of phase propagation.

For propagating waves, frequency generally depends on the wave number of the perturbation as well as the physical properties of the basic state. Thus, since $c_x = \nu/k$, the phase speed also depends on the wave number except in the special case where $\nu \propto k$. For waves in which the phase speed varies with k , the various sinusoidal components of a disturbance originating at a given location are at a later time found in different places. Such waves are referred to as dispersive, and the formula that relates ν and k is called a dispersion relationship. Some types of waves, such as acoustic waves, have phase speeds that are independent of the wave number. In such nondispersive waves, a spatially localized disturbance consisting of a number of Fourier wave components (a wave group) will preserve its shape as it propagates in space at the phase speed of the wave. For dispersive waves, however, the shape of a wave group will not remain constant as the group propagates. Since the individual Fourier components of a wave group may either reinforce or cancel each other, depending on the relative phases of the components, the energy of the group will be concentrated in limited regions.

When waves are dispersive, the speed of the wave group is generally different from the average phase speed of the individual Fourier components. Hence, as shown in Figure 1, individual wave components may move through the group as the group propagates in space. Furthermore, the group generally broadens in the course of time, that is, the energy is dispersed. A familiar example is the wake of a ship, in which individual wave crests are observed to move twice as fast as the wave group.

An expression for the group velocity, which is the velocity at which the observable disturbance (and hence the energy) propagates, can be derived by considering the superposition of

Figure 1 Propagation of a wave group. Heavy line shows group speed; dashed line shows phase speed. Reproduced from Holton, J.R., 1992. *Introduction to Dynamic Meteorology*, 3rd edn. San Diego, CA: Academic Press.

two horizontally propagating waves of equal amplitude but slightly different wavelengths with wave numbers $k \pm \delta k$ and frequencies $\nu \pm \delta \nu$, respectively. The total disturbance is thus given by eqn [4], where it is understood that only the real part of the right-hand side has physical meaning.

$$\psi(x, t) = \exp\{i[(k + \delta k)x - (\nu + \delta \nu)t]\} + \exp\{i[(k - \delta k)x - (\nu - \delta \nu)t]\} \quad [4]$$

Rearranging terms gives eqn [5].

$$\begin{aligned} \psi(x, t) &= \left[e^{i(\delta kx - \delta \nu t)} + e^{-i(\delta kx - \delta \nu t)} \right] e^{i(kx - \nu t)} \\ &= 2\cos(\delta kx - \delta \nu t) e^{i(kx - \nu t)} \end{aligned} \quad [5]$$

The disturbance is the product of a high frequency carrier wave of wavelength $2\pi/k$ whose phase speed, ν/k , is the average for the two Fourier components, and a low frequency envelope of wavelength $2\pi/\delta k$ that travels at the speed $\delta \nu/\delta k$. Thus, in the limit as $\delta k \rightarrow 0$, the horizontal velocity of the envelope, or group velocity, c_{gx} , is simply as given in eqn [6].

$$c_{gx} = \frac{\partial \nu}{\partial k} \quad [6]$$

This result applies generally to arbitrary wave disturbances provided that the wavelength of the wave group, $2\pi/\delta k$, is large compared to the wavelength of a characteristic wave component, $2\pi/k$.

Wave Classification

Wave activity may propagate horizontally and vertically over large distances from wave sources to regions where transience, nonlinear wave breaking, or dissipation causes interactions with the mean flow. Waves can thus provide a strong nonlocal influence on the momentum and heat budgets and on atmospheric transport. The nature of the major types of wave

motions in the atmosphere can be classified according to several wave dualities.

- **Energy source.** Waves can be divided into free modes and forced modes. Free modes are the normal (i.e., resonant) modes of oscillation of the atmosphere. These can be excited by small random forcing, and are limited in amplitude by dissipation. Free planetary waves (so-called Rossby modes) of global extent and periods of about 2, 5, and 16 days have been detected in the atmosphere, and are especially notable in the stratosphere. Most waves important for weather and climate, however, are forced modes. Examples of forced modes are Rossby waves excited by flow over topography or by land-ocean heating contrasts, and gravity waves generated by convection.
- **Horizontal structure.** Waves can be divided into global modes, which can propagate meridionally as well as zonally, and equatorial modes, which are trapped in an equatorial waveguide and propagate zonally along the Equator. Rossby waves are the most important global modes. Kelvin waves (a special type of gravity wave) and Rossby-gravity waves are the most important equatorial modes.
- **Vertical structure.** Waves can be divided into external and internal modes. External modes are vertically trapped; the energy density of such modes decays exponentially in the vertical. Internal modes are vertically propagating (phase surfaces tilt with height); they can transfer momentum and energy vertically over many scale heights. Under suitable conditions, forced Rossby waves, Kelvin waves, Rossby-gravity waves, and gravity waves can all propagate vertically and transfer energy and momentum between the lower atmosphere and the upper atmosphere.

Typical vertical distributions of forced Rossby and gravity wave amplitudes in the extratropics are shown schematically in **Figure 2**. Gravity wave amplitudes increase exponentially with height at all seasons. Forced Rossby waves of planetary scale propagate to high altitudes during the winter season when the mean zonal winds are westerly in the middle atmosphere, but are trapped during the summer when the mean zonal winds are easterly. Synoptic-scale Rossby waves are trapped in the troposphere at all seasons.

Internal Gravity Waves

Basic Properties

Internal gravity waves are vertically propagating waves associated with the buoyancy restoring force in stably stratified fluids. Parcel oscillations in these waves are parallel to the phase lines, and hence perpendicular to the direction of phase propagation as indicated in **Figure 3**. Thus, for example, the phase surface corresponding to the maximum negative temperature perturbation occurs one-quarter cycle after the maximum upward motion, hence coinciding with maximum upward displacement (and adiabatic cooling) of fluid parcels.

The physical mechanism for internal gravity wave propagation can be understood by considering a fluid parcel displaced from its equilibrium altitude. If a parcel is displaced at

Figure 2 Vertical profiles of characteristic horizontal velocity amplitudes for various types of atmospheric waves and the mean zonal flow. Solid lines: planetary waves (a) summer, (b) winter. Dashed line: zonal mean. Dotted line: synoptic scale. Dotted-dashed line: gravity waves.

a distance δs along a line tilted at an angle α to the vertical, as shown in Figure 4, it will undergo a vertical displacement $\delta z = \delta s \cos \alpha$. For such a parcel, the buoyancy force per unit mass, which is directed in the vertical, is just $-N^2 \delta z$, where

Figure 4 Parcel oscillation path (heavy arrow) for pure gravity waves with phase line tilted at an angle to the vertical. Reproduced from Holton, J.R., 1992. Introduction to Dynamic Meteorology, 3rd edn. San Diego, CA: Academic Press.

$N^2 = -g d \ln \bar{\rho} / dz$ is the square of the buoyancy frequency (with $\bar{\rho}$ the equilibrium density). The component of the buoyancy force perpendicular to the parcel path is balanced exactly by the wave's pressure gradient force, which is itself perpendicular to the parcel path as shown in Figure 3. The parcel acceleration is thus given by the component of the buoyancy force parallel to the parcel path (eqn [7]).

$$-N^2 (\delta s \cos \alpha) \cos \alpha = -(N \cos \alpha)^2 \delta s \quad [7]$$

The momentum equation for the parcel oscillation is then given by eqn [8].

$$\frac{d^2(\delta s)}{dt^2} = -(N \cos \alpha)^2 \delta s \quad [8]$$

This has the general solution $\delta s = \exp[\pm i(N \cos \alpha)t]$. Thus, the parcel executes a simple harmonic oscillation at the frequency $\nu = N \cos \alpha$. This frequency depends only on the static stability (measured by the buoyancy frequency N) and the angle of the phase lines to the vertical.

Dispersion Relationship

In the absence of rotation, the parameters governing two-dimensional buoyancy waves approximately satisfy the dispersion relation of eqn [9].

$$(\nu - \bar{u}k)^2 \equiv \hat{\nu}^2 = N^2 k^2 (m^2 + k^2)^{-1} \quad [9]$$

Here $k = 2\pi/L_x$ and $m = 2\pi/L_z$ are the zonal and vertical wave numbers, respectively, L_x and L_z are the zonal and vertical wavelengths, respectively, and $\hat{\nu} = \nu - \bar{u}k$. The parameter $\hat{\nu}$, which is the frequency relative to the mean flow, is referred to as the Doppler shifted frequency or intrinsic frequency. For most observed gravity waves, eqn [10] applies.

$$\frac{\hat{\nu}}{N} \approx \pm \frac{k}{m} \approx \pm \cos \alpha \quad [10]$$

α is again the angle of phase lines to the vertical. Thus the ratio of the intrinsic wave frequency to the buoyancy frequency determines the slope of the phase lines. By convention, the zonal wave number k is always positive, so if the frequency ν is positive, the zonal phase speed $c_x = \nu/k$ is also positive. For waves in which phase lines slope upward in the positive x direction (as in Figure 2) the vertical wave number m must be negative. This can be easily verified by noting that along lines of constant phase eqn [11] applies, so that for t constant and

Figure 3 Schematic cross section showing phase relationships among the geopotential, temperature, and velocity perturbations for an internal gravity wave. Thin arrows indicate the perturbation velocity field; and blunt solid arrows show the phase velocity. Shading shows regions of upward motion.

k positive, m must be negative if ϕ is to be constant for x and z both increasing.

$$\phi = kx + mz - vt = \text{constant} \quad [11]$$

In this case the negative root must then be taken in eqn [10], since frequency is positive.

Energy propagates with the group velocity $c_g \equiv (c_{gx}, c_{gz})$, which for the dispersion relation eqn [10] can be expressed as eqn [12].

$$(c_{gx}, c_{gz}) = \left(\frac{\partial v}{\partial k}, \frac{\partial v}{\partial m} \right) = (\bar{u}, 0) \pm \frac{N}{m^2} (m, -k) \quad [12]$$

For the eastward-propagating wave of Figure 3 the negative root applies and m is negative, so that the group velocity relative to the mean flow $\bar{u}$ is eastward and upward. Since $|c_{gz}/(c_{gx} - \bar{u})| = |k/m|$, the group velocity vector relative to the mean flow is parallel to lines of constant phase. Thus, energy propagates eastward and upward relative to the mean flow as phase propagates eastward and downward phase and energy propagate in opposite directions in the vertical!

Most gravity waves have sources at the surface or in the troposphere and propagate energy upward into the stratosphere. They thus have downward phase propagation as in Figure 3. Gravity waves of periods greater than a few hours are influenced by the Coriolis effect, which causes parcel trajectories to be elliptical rather than linear. For a detailed discussion of these waves, see **Gravity Waves: Buoyancy and Buoyancy Waves: Theory**.

Rossby (Planetary) Waves

The wave type that is of most importance for large-scale meteorological processes in the troposphere and the stratosphere is the Rossby wave or planetary wave. In its most general sense the Rossby wave owes its existence to the latitudinal gradient of potential vorticity. This gradient causes fluid parcels that are displaced in latitude to develop anomalous potential vorticity, which induces velocity anomalies that in turn produce further anomalies in potential vorticity. For an illustration of the mechanism of the Rossby wave, see **Dynamical Meteorology: Overview**.

Barotropic Rossby Waves

The simplest Rossby waves occur in the case in which motions are nondivergent and barotropic (i.e., independent of depth). Such conditions are a reasonable first approximation for the flow at the 500 hPa level (mid-troposphere). The dispersion relationship for barotropic Rossby waves may be derived formally by finding wave-type solutions of the linearized barotropic vorticity equation. The barotropic vorticity equation states that the vertical component of absolute vorticity, $\zeta + f$, is conserved following the horizontal motion. Here ζ is the relative vorticity owing to the winds and f is the planetary vorticity (or Coriolis parameter) due to the rotation of the Earth. The analysis is facilitated by the use of the mid-latitude β -plane approximation. In this approximation, the variation of the planetary vorticity with latitude is approximated by expanding the latitudinal dependence of the Coriolis parameter, $f = 2\Omega \sin \phi$ (where Ω is the angular velocity of rotation of the Earth and ϕ

is latitude) in a Taylor series about a reference latitude ϕ_0 and retaining only the first two terms of the series to yield $f = f_0 + \beta y$, where f_0 and β are, respectively, the values of f and df/dy evaluated at the reference latitude ϕ_0 . With this approximation, eqn [13] gives the barotropic vorticity equation.

$$\left(\frac{\partial}{\partial t} + u \frac{\partial}{\partial x} + v \frac{\partial}{\partial y} \right) \zeta + \beta v = 0 \quad [13]$$

The flow is assumed to consist of a constant basic state zonal velocity plus a small horizontal perturbation. Since the horizontal velocity in the barotropic model is nondivergent, the perturbation velocity can be represented in terms of a perturbation stream function (eqn [14]).

$$u' = -\frac{\partial \psi'}{\partial y} \quad v = v' = \frac{\partial \psi'}{\partial x} \quad [14]$$

$$\zeta = \zeta' = \left(\frac{\partial v'}{\partial x} - \frac{\partial u'}{\partial y} \right) = \nabla^2 \psi'$$

The linearized form of eqn [13] is then given by eqn [15].

$$\frac{\partial}{\partial t} + \bar{u} \frac{\partial}{\partial x} \nabla^2 \psi' + \beta \frac{\partial \psi'}{\partial x} = 0 \quad [15]$$

A solution of eqn [15] can be obtained in the form of eqn [16].

$$\psi' = \text{Re} \{ \Psi \exp[i(kx + ly - vt)] \} \quad [16]$$

Here k and l are wave numbers in the zonal and meridional directions, respectively. Substituting eqn [16] into eqn [15] and solving for $c_x = v/k$ yields eqn [17].

$$c_x = \bar{u} - \frac{\beta}{k^2 + l^2} \quad [17]$$

According to eqn [17] the zonal phase propagation of Rossby waves is always westward relative to the mean zonal flow and depends inversely on the square of the horizontal wave number. Therefore, Rossby waves are dispersive. This result is consistent with the fact that the advection of planetary vorticity, which tends to make disturbances propagate westward, increasingly dominates over relative vorticity advection as the wavelength of a disturbance increases. For a typical mid-latitude synoptic-scale disturbance, with similar meridional and zonal scales ($l \approx k$) and zonal wavelength of order 6000 km, the Rossby wave phase speed relative to the zonal flow calculated from eqn [10] is approximately -8 m s^{-1} . Since the mean zonal wind near the 500 hPa level in mid-latitudes is generally greater than 8 m s^{-1} , synoptic-scale Rossby waves usually move eastward, but at a phase speed relative to the ground that is somewhat less than the mean zonal wind speed.

For longer wavelengths, the westward Rossby wave phase speed may be large enough to balance the eastward advection by the mean zonal wind so that the resulting disturbance is stationary relative to the surface of the earth. From eqn [17] the barotropic Rossby wave solution is stationary relative to the ground ($c_x = 0$) when eqn [18] holds.

$$(k^2 + l^2) = \frac{\beta}{\bar{u}} \quad [18]$$

The group velocity for barotropic Rossby waves is given by eqn [19].

$$(c_{gx}, c_{gy}) = \left(\frac{\partial v}{\partial k}, \frac{\partial v}{\partial l} \right) = \left[\bar{u} + \frac{\beta(k^2 - l^2)}{(k^2 + l^2)^2}, \frac{2\beta kl}{(k^2 + l^2)^2} \right] \quad [19]$$

Unlike the Rossby wave phase speed, which is always westward relative to the mean flow, the zonal component of group velocity may be either eastward or westward relative to the mean flow, depending on the ratio of the zonal and meridional wave numbers. Eastward (i.e., downstream) propagation is believed to be important for the development and evolution of tropospheric weather disturbances in the westerlies of the extratropical regions. For stationary modes, the phase velocity relative to the mean flow is westward, but the zonal component of group velocity is always eastward, as can be seen by substituting $\bar{u} = \beta/(k^2 + l^2)$ into eqn (19). In that case Rossby wave dispersion produces downstream propagation of energy.

Stationary Rossby modes (i.e., modes with $c_x = 0$) are strongly excited by flow over major mountain ranges. Such waves can be illustrated by the barotropic vorticity equation if a term is included to account for dilution and concentration of vorticity due to the divergence and convergence associated with flow forced over the mountains. For typical mid-latitude zonal winds the stationary Rossby wave pattern excited by flow over

the Rockies and Himalayas (Figure 5) features lee-side troughs in agreement with observations.

Vertically Propagating Rossby Waves

Vertically propagating Rossby waves are forced modes generated by flow over continental-scale topography, by continent-ocean heating contrasts, and by nonlinear interactions among transient tropospheric wave disturbances. Such motions are approximately governed by the conservation following the geostrophic wind of a dynamical field called quasigeostrophic potential vorticity.

The linearized quasigeostrophic potential vorticity equation for a basic state with constant mean zonal wind $\bar{u}$ can be expressed as in eqn [20], where q' is given by eqn [21].

$$\frac{\partial}{\partial t} + \bar{u} \frac{\partial q'}{\partial x} + v' \beta = 0 \quad [20]$$

$$q' = \nabla^2 \psi' \frac{f_0^2}{\rho_0} \frac{\partial}{\partial z} \left(\frac{\rho_0}{N^2} \frac{\partial \psi'}{\partial z} \right) \quad [21]$$

Here ρ_0 , the reference density, decreases with height exponentially at a constant scale height H , so that $\rho_0 = \rho_s \exp(-z/H)$ and ρ_s the density at sea level. Equation [20] states that the rate of change of q following the mean flow $\bar{u}$ is given by the advection of the planetary vorticity by the disturbance meridional wind component. Equation [20] has solutions in the form of [22], where k , l , and m are the zonal, meridional, and vertical wave numbers, respectively; and v is the frequency of the waves.

$$\psi' = A \exp(i(kx + ly + mz - vt) + \frac{z}{2H}) \quad [22]$$

Note that the factor $\exp(z/2H)$, which is proportional to $\rho_0^{-1/2}$, is introduced to account for the fact that in this simple model the perturbation stream function for vertically propagating waves grows in height as the inverse square root of density. Substituting eqn [22] into eqn [20] and solving for m^2 yields eqn [23] where again $c_x = v/k$ is the zonal phase speed relative to the ground.

$$m^2 = \frac{N^2}{f_0^2} \left[\frac{\beta}{\bar{u} - c_x} - (k^2 + l^2) \right] - \frac{1}{4H^2} \quad [23]$$

For known c_x , k , and l , eqn [23] gives the vertical structure of the waves. For forced wave solutions the wave frequency is specified as that of the forcing. Thus, for topographically forced solutions the zonal phase speed relative to the ground is zero ($c_x = 0$), and $m^2 > 0$ only if eqn [24] is satisfied.

$$0 < \bar{u} < u_c, \text{ where } u_c = \beta \left[k^2 + l^2 + \frac{f_0^2}{4N^2 H^2} \right]^{-1} \quad [24]$$

For $m^2 > 0$ waves can propagate vertically, while for $m^2 \leq 0$ the waves are trapped. Thus, for stationary waves, vertical propagation exists only in the presence of mean westerly winds that are less than a critical value, u_c . This result is referred to as the Charney–Drazin criterion. For example, for a wave with large meridional scale, $l \approx 2\pi/(12\,000 \text{ km})$ and planetary wave number 1 ($k = a^{-1}$), this theory gives $u_c \approx 60 \text{ m s}^{-1}$. More accurate calculations with spherical geometry and realistic winds give $u_c \approx 100 \text{ m s}^{-1}$. It is clear from eqn [24] that u_c decreases rapidly as k and l increase, i.e., the critical value is

Figure 5 Upper panel shows the longitudinal variation of the stationary barotropic Rossby wave disturbance geopotential height field (solid line) compared with the observed 500 hPa height disturbance at 45° N in January (dashed line). The lower panel shows the topography profile used in the computation. Reproduced from Held, I.M., 1983. In: Hoskins, B.J., Pearce, R., (eds.) *Large-Scale Dynamical Processes in the Atmosphere*. New York, NY: Academic Press.

determined largely by horizontal wave scales. In practice only zonal wave numbers 1 and 2 propagate significantly into the extratropical stratosphere, and this happens only in the winter hemisphere where $\bar{u} > 0$. Therefore, the Charney–Drazin criterion provides an approximate explanation for the absence of stationary planetary waves in the summer stratosphere (where winds are easterly) and the dominance of waves of zonal wave numbers 1 and 2 in the winter stratosphere.

Equatorial Waves

The change of sign of the Coriolis parameter at the Equator leads to a special class of large-scale atmospheric waves that are trapped laterally in the equatorial region but propagate zonally and vertically. Such waves have important consequences for the circulation of the equatorial middle atmosphere. Equatorial waves are most easily analyzed by utilizing an equatorial β -plane approximation, in which the Coriolis parameter is assumed to vary linearly with distance from the equator so that $f = \beta y$, where $\beta \equiv (df/dy)_{\phi=0} = 2\Omega/a$, with a the radius of the Earth.

Solutions for zonally propagating wave disturbances on an equatorial β -plane in a basic state at rest can be expressed in the form of eqn [25].

$$v' = \text{Re} \left\{ \Psi(y) \exp \left[i(kx + mz - \nu t) + \frac{z}{2H} \right] \right\} \quad [25]$$

Again it is assumed that $k > 0$, so that $\nu > 0$ implies eastward propagation relative to the ground at phase speed $c_x = \nu/k$.

The Meridional Structure

The meridional structure in eqn [25] can be determined by letting λ be given by eqn [26] and defining the transformed variable $\xi = (\beta|m|/N)^{1/2}y$.

$$\lambda^2 = \frac{N}{\beta|m|} \left(\frac{m^2 \nu^2}{N^2} - k^2 - \frac{k\beta}{\nu} \right) \quad [26]$$

It can then be shown that Ψ satisfies eqn [27], which is just the Schrodinger equation for a quantum harmonic oscillator.

$$\frac{d^2 \Psi}{d\xi^2} + (\lambda^2 - \xi^2) \Psi = 0 \quad [27]$$

This equation is analogous to the governing equation for a simple harmonic oscillator, eqn [28], where I^2 is a positive constant.

$$\frac{d^2 \Psi}{dy^2} + I^2 \Psi = 0 \quad [28]$$

The equatorial case given by eqn [27] differs from the simple harmonic oscillator in that oscillating solutions exist only for $\xi^2 < \lambda^2$ (with $\lambda^2 > 0$), while exponential behavior occurs otherwise. Solutions of eqn [27] that satisfies the condition of equatorial trapping ($\Psi \rightarrow 0$ as $\xi \rightarrow \pm\infty$) exist if and only if $\lambda^2 = 2n + 1$, where $n = 0, 1, 2, \dots$. These solutions are the Hermite functions defined by eqn [29].

$$\Psi_n = e^{-\xi^2/2} H_n(\xi) \quad [29]$$

$H_n(\xi)$ is the Hermite polynomial of order n , so that successive values are given by eqn [30].

$$H_0(\xi) = 1 \quad H_1(\xi) = 2\xi \quad H_2(\xi) = 4\xi^2 - 2 \quad [30]$$

Substitution of eqn [29] into eqn [27] then yields the dispersion relation (eqn [31]).

$$\frac{N}{\beta|m|} \left(\frac{m^2 \nu^2}{N^2} - k^2 - \frac{k\beta}{\nu} \right) = 2n + 1 \quad [31]$$

Rossby-Gravity Waves

The lowest meridional mode solution of eqn [31], the $n = 0$ mode, is called a Rossby-gravity wave. It has a meridional velocity perturbation, v' , that is symmetric about the Equator. For this mode eqn [32] applies, which determines the vertical wave number for specified zonal wave number and frequency.

$$|m| = \frac{N}{\nu^2} (\beta + \nu k) \quad [32]$$

Letting $s = ka$, where s is the number of wavelengths around a latitude circle ($s = 0, 1, 2, \dots$), and recalling that $\beta = 2\Omega/a$, eqn [32] implies that with $\nu < 0$ (corresponding to the observed westward propagation of these modes) a solution exists only for $|\hat{\nu}/\Omega| < 2/s$. For $s = 4$, $|\hat{\nu}/\Omega| < 1/2$, so that the period in this case must be greater than 2 days.

In terms of the original y coordinate, the solution for the meridional velocity perturbation in the Rossby-gravity mode can be expressed as eqn [33].

$$\tilde{v} = V_0 \exp \left[-\frac{(1 + kv\beta^{-1})\beta^2 y^2}{2\nu^2} \right] \quad [33]$$

The corresponding solutions for the zonal wind and geopotential perturbations are given by eqn [34].

$$\begin{aligned} \begin{Bmatrix} \tilde{u} \\ \tilde{\Phi} \end{Bmatrix} &= V_0 \begin{Bmatrix} -i\beta y(1 + kv\beta^{-1})\nu^{-1} \\ +i\nu y \end{Bmatrix} \\ &\times \exp \left[-\frac{(1 + kv\beta^{-1})\beta^2 y^2}{2\nu^2} \right] \end{aligned} \quad [34]$$

For observed Rossby-gravity waves in the equatorial stratosphere, $\nu \sim 2\pi/(4\text{days})$, $s = 4$, and $L_z = 2\pi/m \sim 6\text{--}8$ km. The horizontal and vertical structures of the Rossby-gravity wave are shown in Figures 6 and 7, respectively.

Kelvin Waves

There is an important type of equatorial wave in which the meridional velocity perturbation vanishes ($v' = 0$). For this

Figure 6 Latitude-longitude section showing horizontal velocity and geopotential perturbations associated with an equatorial Rossby-gravity wave.

Figure 7 Longitude–height section along the equator showing geopotential, temperature, and wind perturbations for a thermally damped Rossby-gravity wave. Heavy wavy lines indicate material lines. Areas of high pressure are shaded. Small thin arrows indicate zonal and vertical velocity perturbations, with length proportional to wave amplitude, which decrease with height owing to damping. mode it turns out that eqn [35] applies, which is the same as the dispersion equation for an eastward-propagating internal gravity wave.

$$v = \pm \frac{kN}{m} \quad [35]$$

The zonal wind disturbance for this mode has a Gaussian distribution about the Equator (eqn [36]).

$$\tilde{u} = u_0 \exp \left[\frac{-\beta y^2 k^2}{2v} \right] \quad [36]$$

Temperature and pressure are similarly symmetric about the Equator. Note that this solution requires that $v/k = c_x > 0$, otherwise it would grow without bound away from the Equator, which explains why only eastward-propagating Kelvin waves are allowed.

For observed Kelvin waves in the equatorial stratosphere, eqn [37] is satisfied.

$$\frac{v}{k} \sim 30 \text{ m s}^{-1} \quad \text{so} \quad L_z = \frac{2\pi}{|m|} \sim 12 \text{ km} \quad [37]$$

The horizontal and vertical structures for the Kelvin mode are shown in **Figures 8 and 9**, respectively. The vertical structure is the same as that for a two-dimensional internal gravity wave. The meridional width for observed Kelvin waves is of order Y_L given by eqn [38].

$$Y_L = \left| \frac{2v}{\beta k} \right|^{1/2} = \left| \frac{2c_x}{\beta} \right|^{1/2} \sim 2000 \text{ km} \quad [38]$$

Kelvin waves are a significant source of westerly momentum for driving the westerly phase of the equatorial stratospheric quasi-biennial oscillation (QBO).

PREFACE TO THE FIRST EDITION

A half century ago the American Meteorological Society published the *Compendium of Meteorology*, which in a single volume of 1334 pages summarized the state of understanding of the atmosphere at that time. A perusal of the contents of that volume indicates that although a broad range of topics was covered, the vast bulk of the volume was devoted to traditional meteorological topics such as atmospheric dynamics, cloud physics, and weather forecasting. Barely 4 percent of the volume was devoted to articles related to atmospheric chemistry or air pollution and, of course, none of the volume was devoted to techniques such as satellites and remote sensing.

As Sir John Mason aptly notes in his foreword to the present work, the atmospheric sciences have expanded in scope enormously over the past 50 years. Topics such as atmospheric chemistry and global climate change, of only marginal interest 50 years ago, are now central disciplines within the atmospheric sciences. Increasingly, developing areas within the atmospheric sciences require students, teachers, and researchers to familiarize themselves with areas far outside their own specialties. This work is intended to satisfy the need for a convenient and accessible references source covering all aspects of atmospheric sciences. It is written at a level that allows undergraduate science and engineering students to understand the material, while providing active researchers with the latest information in the field.

More than 400 scientists, from academia, government, and industry have contributed to the 330 articles in this work. We are very grateful to these authors for their success in providing concise and authoritative summaries of complex subjects. As editors, we have benefited from the chance to learn from these articles, and we believe that all students and active scientists who want to increase their knowledge of the atmosphere will benefit enormously from access to this work.

We are also grateful to the 31 members of the Editorial Advisory Board who have guided us in our coverage of the very broad range of topics represented in this encyclopedia. Their willingness to suggest topics and authors, and to carefully review draft articles has contributed significantly to our success.

The production of this multivolume encyclopedia would not have been possible without the dedicated work of the staff of the Major Reference Works group at Academic Press. We are especially grateful to the Major Reference Work Development Manager, Colin McNeil, who has worked closely with us during the entire process. Finally, we appreciate the liberal use of color figures in the printed encyclopedia.

James R Holton, Judith A Curry, and John Pyle

PREFACE TO THE SECOND EDITION

Since the publication of the first edition of the *Encyclopedia of Atmospheric Sciences*, significant advances in research have been achieved all across the broad and expanding spectrum of the field and related disciplines. In particular, climate science with primary input from the atmospheric research emerges as a new field and integrator of interlocking peripheral disciplines over the last decade. These events have demanded the solicitation of new and updated articles for the 2003 edition. Some articles from the earlier publication were judged to be of such a fundamental and enduring nature that they did not require modification. But huge amounts of new information from Earth-orbiting satellite observatories have brought much new insight to the field. In addition there are new findings in many areas such as the latest simulations of meteorological and climatic processes of interest as well as simulations and observations of the composition and interaction of the field's chemical constituents. While interest in the ozone hole and its ramifications may have reached a plateau, ever more understanding of the stratosphere and its role in climate change emerges. The study of past climates provides new means of testing climate models and theories. In weather prediction we see new progress on how data are to be better assimilated for much improved initialization of the forecast model leading to the promise of more accurate predictions of severe weather and tropical cyclones over longer lead times. These are just a few of the new features of the second edition.

The editors of the second edition are greatly indebted to our predecessors in the first edition. They set the outline of topics and solicited the original authors, while establishing a high standard for the content of this publication. In many cases we decided to reprint those articles or request only minor updates. Nevertheless, many articles in this edition are entirely original, based on which we also made significant reorganization of the content. We are proud of our product and hope it provides the same assistance to students, researchers, and practitioners throughout the science and engineering communities.

Editors of the second edition
Gerald R North
Fuqing Zhang
John Pyle

EDITOR BIOGRAPHIES

Gerald R North received his PhD in theoretical physics from the University of Wisconsin in 1966. After postdoctoral research at the University of Pennsylvania he became a faculty member in physics at the University of Missouri–St. Louis. He shifted his research focus to climate science research during his sabbatical year at the National Center for Atmospheric Research, where he won the Outstanding Paper Award in 1975. He moved to NASA Goddard Space Flight Center (GSFC) in 1978 where he was awarded the NASA Medal for Research Excellence. During his stay at GSFC, he was the proposer and first study scientist for the Tropical Rainfall Measuring Mission, which was launched in 1997 and is still orbiting in 2014.

He moved to Texas A&M University in 1986 as a university distinguished professor of atmospheric sciences where he served as department head from 1995 to 2003. He has served as editor-in-chief of the *Reviews of Geophysics* and is recognized as one of the most cited authors in geosciences (Web of Science). He has chaired and/or served on a number of national committees and is a Fellow of the American Geophysical Union, American Meteorological Society (AMS) and the American Association for the Advancement of Science, and winner of the Jule Charney Award for Research (AMS).

He has published about 150 refereed papers not including many book chapters and reviews. His books include *Paleoclimatology*, co-authored with Thomas Crowley, and *An Introduction to Atmospheric Thermodynamics* co-authored with Tatiana Erikhimova.

North's interests are focused on the use of mathematical and statistical tools to solve climate problems over a wide range of issues including: analytical solutions of simplified energy balance climate models, use of random field techniques in representing and interpreting climate data and model simulations, detection of deterministic signals in climate change, statistical analysis satellite remote sensing for mission planning and analysis of data, paleoclimate problems using simplified climate models.

John Pyle obtained a BSc in Physics at Durham University before moving to Oxford where he completed a DPhil in Atmospheric Physics, helping to develop a numerical model for stratospheric ozone studies. After a short period at the Rutherford Appleton Laboratory he moved to a lectureship at Cambridge University in 1985. In 2000 he was appointed professor of atmospheric science and since 2007 has been the 1920 professor of physical chemistry. He is a Professorial Fellow at St Catharine's College. He has been a codirector of Natural Environment Research Council's National Centre for Atmospheric Science, where he is currently Chief Scientist.

His research focuses on the numerical modelling of atmospheric chemistry. Problems involving the interaction between chemistry and climate have been addressed; these range from stratospheric ozone depletion to the changing tropospheric oxidizing capacity and have included the environmental impact of aviation, land use change, biofuel technologies, and the hydrogen economy. He has studied palaeochemistry problems as well as the projected atmospheric composition changes during the current century. He has published more than 250 peer reviewed papers.

He played a major role in building an EU stratospheric research programme in the 1990s, coordinating several major field campaigns. He has contributed to all the WMO/UNEP assessments on stratospheric ozone since the early 1980s and is now one of the four international cochairmen

of the Scientific Assessment Panel, responsible for these assessments. He was a convening lead author in the IPCC Special report "Safeguarding the ozone layer and the global climate system," published in 2006.

He was elected Fellow of the Royal Society in 2004 and an American Geophysical Union Fellow in 2011. He was awarded the Cambridge ScD degree in 2012. Other honours and awards include membership of Academia Europaea (1993), Royal Society of Chemistry (Interdisciplinary award, 1991, and John Jeyes lectureship, 2008), and the Royal Meteorological Society Adrian Gill Prize, in 2004.

Fuqing Zhang is a professor with tenure in the Department of Meteorology at the Pennsylvania State University, with a joint appointment in the Department of Statistics, along with an endowed position as the E Willard & Ruby S Miller Faculty Fellow at the College of Earth and Mineral Sciences at the Pennsylvania State University. His research interests include atmospheric dynamics and predictability, data assimilation, ensemble forecasting, tropical cyclones, gravity waves, mountain plains and sea-breeze circulations, warm-season convection, and regional-scale climate. He earned his BS and MS in meteorology from Nanjing University, China in 1991 and 1994, respectively, and his PhD in atmospheric science in 2000 from North Carolina State University.

He spent seven years as an assistant and then associate professor at Texas A&M University before coming to Penn State University as a full professor in 2008. In 2000, he spent a year and a half as a postdoctoral fellow at the National Center for Atmospheric Research. He also held various visiting scholarship appointments at various academic and research institutions including the National Center for Atmospheric Research in Boulder, Colorado; the Navy Research Laboratory in Monterey, California; NOAA/AOML Hurricane Research Division, Miami, Florida; Peking University and Nanjing University, China; the Chinese State Key Laboratory of Severe Weather in Beijing, China; and Laboratoire de Meteorologie Dynamique, École Normale Supérieure in Paris, France.

He has authored/co-authored about 130 peer reviewed journal publications and has given more than 160 keynote speeches or invited talks at various institutions and meetings. He has served as principal investigator/co-principal investigator for 30 federal or state-sponsored research grants. He has chaired/cochaired more than 10 scientific meetings or workshops. He also served on various review or advisory panels for numerous organizations that include National Science Foundation, Office of Naval Research, NASA, NOAA, and National Academies. He has also served as editor of several professional journals including *Monthly Weather Review*, *Science China*, *Atmospheric Science Letter*, *Acta Meteorologica Sinica*, and *Computing in Science & Engineering*.

He has also received numerous awards for his research and service. Notably, in 2007 he received the **Outstanding Publication Award** from the National Center for Atmospheric Research. In 2009, was the sole recipient of the American Meteorological Society's 2009 **Clarence Leroy Meisinger Award** "for outstanding contributions to mesoscale dynamics, predictability, and ensemble data assimilation." Most recently, he received the 2014 American Meteorological Society's **Banner Miller Award** "for valuable insights into incorporating real-time airborne Doppler radar measurements via ensemble data assimilation, leading to improvements in forecasts of tropical cyclone track and intensity."

GUIDE TO USING THE ENCYCLOPEDIA

Structure of the Encyclopedia

The material in the encyclopedia is not arranged by ordinary alphabetical order, but by alphabetical order according to 49 principal topic areas taken to allow all papers belonging to each principal topic to appear together in the same volume. Within each principal subject, article headings are also arranged alphabetically, except where logic dictates otherwise. For example, overview articles appear at the beginning of a section.

There are four features that help you find the topic in which you are interested:

- i. the contents list
- ii. cross-references to other relevant articles within each article
- iii. a full subject index
- iv. contributors

i. Contents List

The contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia. It includes both the volume number and the page number of each entry.

ii. Cross-references

All of the entries in the encyclopedia have been cross-referenced. The cross-references, which appear at the end of an article as a See also list, serve four different functions:

- i. To draw the reader's attention to related material in other entries

- ii. To indicate material that broadens and extends the scope of the article
- iii. To indicate material that covers a topic in more depth
- iv. To direct readers to other articles by the same author(s)

Example

The following list of cross-references appears at the end of the article.

See also: **Biogeochemical Cycles:** Biogeochemistry of Iodine. **Stratospheric Chemistry Topics:** HO_x; Halogen Sources, Natural (Methyl Bromide and Related Gases); Halogens; Hydrogen Budget; Overview; Reactive Nitrogen (NO_x and NO_y).

iii. Index

The index includes page numbers for quick reference to the information you are looking for. The index entries differentiate between references to a whole article, a part of an article, and a table or figure.

iv. Contributors

At the start of each volume there is list of the authors who contributed to that volume.

Synopsis

The Earth–ionosphere cavity, composed of a thin insulator (the atmosphere) confined between two spherical conductors (the Earth and the ionosphere), provides the natural framework for both the DC and AC global circuits. The DC global circuit involves a nominal voltage drop of 250 kV between Earth and ionosphere. The AC global circuit is an electromagnetic wave phenomenon known as Schumann resonances. The historical discovery of these phenomena and their salient features is reviewed. The source currents for the DC and AC global circuits are different, but cloud-to-ground lightning is a source common to both. Accordingly, the variations in amplitude of the two global circuits are expected to be correlated but not identical. The value of monitoring the global circuit for climate change applications is emphasized, but robust measurement schemes need to be implemented.

Introduction

We live in a thin layer of air glued to the Earth's surface by gravity. This gaseous atmosphere is composed largely of neutral molecules of oxygen and nitrogen and as a consequence is an electrical insulator. The atmosphere is bathed in radiation – ultraviolet (UV) radiation from the Sun and cosmic radiation from deep space. This radiation ionizes the atmosphere and makes it a good electrical conductor at upper levels where the radiation is more energetic. The Earth beneath the atmosphere is abundant in liquid water. All water contains ions in solution, and the ions provide conduction. Three-quarters of the Earth's surface is covered with conductive seawater. Liquid water is also present virtually everywhere on land, permeates the cracks and joints within the Earth's crust, and makes landmasses electrical conductors too. The thin layer of insulating air sandwiched between these two conductors forms the medium for the global electrical circuit. For the so-called 'DC' global circuit, this medium is a giant spherical capacitor. For the 'AC' global circuit, otherwise called the Schumann resonances, the medium is an electromagnetic waveguide.

Historical Development

The development of ideas on the DC global circuit received great impetus from three giants of research in atmospheric

electricity: Benjamin Franklin, William Thomson (Lord Kelvin), and C.T.R. Wilson. Their three contributions, which dominated each of three successive centuries, are discussed in turn.

Franklin can be credited with the first enunciation of a global flow of moist, electrified air. His concept is best discussed around his own picture (**Figure 1**), as presented to the Royal Academy of Sciences in Paris in 1779. Warm, moist air ascends in the tropics and descends in the polar regions. This cloudy air was believed to deliver electricity to the cold polar ice cap on snow, where it would accumulate until breakdown of the rarefied upper atmosphere occurred in the form of the aurora. While this explanation for the aurora is now known to be flawed, the postulated role for the tropics and the picture of the large-scale circulation of the atmosphere were clearly prescient.

Lord Kelvin, 100 years later developed potential theory, a mathematical tool needed for theoretically underpinning the global circuit. Remarkably, more than 40 years before the conductive ionosphere was postulated by A. Kennelly and O. Heaviside in 1902, Kelvin advanced the spherical capacitor picture for the global circuit. His expectation for an outer conductor was based on his knowledge that rarefied air of the upper atmosphere was a poor insulator in comparison with air at the Earth's surface. He also advocated organized measurements of the Earth's electric field, and this suggestion undoubtedly motivated subsequent electrical observations from the research vessels *Carnegie* and *Maude* by the Carnegie

Institution. Kelvin undertook his own surface measurements of potential gradient, verified that the Earth carried a negative charge, and concluded that the global circuit peaked in winter, a result now believed to be dominated by local effects. He also prophesied the use of electrical measurements for purposes of weather prediction.

There can be no doubt that electric indications, when sufficiently studied, will be found important additions to our means for prognosticating the weather and the speaker hoped soon to see the atmospheric electrometer generally adopted as a useful and convenient weather glass.

Measurements by Wilson of the field changes associated with lightning in thunderclouds led him to conclude that the polarity of thunderclouds was systematically positive in upper levels and negative at lower levels. Wilson was also engaged with measurements of the currents flowing to Earth during periods of fair weather. The observation of the transatlantic propagation of radio waves in 1903 by G. Marconi verified the presence of the conductive ionosphere. This collective information led Wilson in 1920 to formulate his famous hypothesis for the global electrical circuit: thunderstorms are batteries and drive current upward to the conductive ionosphere where it spreads out to return to Earth in fair weather regions, as illustrated in Figure 2. Wilson's idea led F. J. W. Whipple to compare the universal time (UT) variation of electric field over the oceans, now referred to as the 'Carnegie curve,' with the UT diurnal variation of thunder areas on a global basis, as shown in Figure 3. Three major tropical continental zones are activated sequentially by the surface heating associated with the passage of the Sun. The similarity in phase between these two curves has long stood as key

Figure 2 Simple illustration of the operation of the DC global circuit with electrified clouds as generators and a return current to earth in fair weather regions.

Figure 3 Comparisons of the UT variation of electric field over the ocean (the Carnegie curve) and the UT variation of thunder areas world-wide. Adapted from Whipple, J.N., 1929. On the association of the diurnal variation of electric potential gradient in fine weather with the distribution of thunderstorms over the globe. *Quarterly Journal of the Royal Meteorological Society* 55, 1–17.

substantiating evidence for the Wilson's global circuit hypothesis. Additional support came in 1950 when O. Gish and G. Wait measured upward currents over thunderstorms from an airplane. More recent measurements have shown upward currents over showerclouds.

Wilson's student T.W. Wormell later extended the surface measurements of current and formulated a statistical charge 'balance sheet' for the global circuit. These results showed that point discharge current dominated over the lightning current in modulating the negative charge transfer to the Earth's surface by electrified storms.

The first coordinated measurements of the global circuit were made by R. Muhleisen, one set from Germany and another from a ship in the Atlantic Ocean. These balloon measurements integrated the vertical electric field in the

atmosphere to provide the so-called ionospheric potential of the global circuit. The simultaneous soundings at two locations agreed to within 5% in three-quarters of the measurements, providing considerable support for the worldwide nature of the global circuit response. Extensive measurements of the DC circuit were also carried out by R. Markson using instrumented aircraft and with balloons from stations in Massachusetts and Australia with similar correlated results, and with diurnal variations that closely follow the classical Carnegie curve.

The first suggestion that the spherical capacitor of the DC global circuit also served as an electromagnetic waveguide appeared when in 1952 W. Schumann postulated the existence of electromagnetic resonances maintained by global lightning activity. Partial experimental verification of the resonances was obtained by Schumann's student H. Koenig in Munich in the late 1950s. M. Balser and C. Wagner of the MIT Lincoln Laboratory verified the multimodal resonances with the first spectral measurements in 1960. Transient excitations of the Schumann resonances by single extraordinarily energetic flashes were reported in the early 1970s by D.L. Jones and his colleagues.

Structure and Operation of the DC Global Circuit

The conductivity structure of the giant spherical capacitor and electromagnetic waveguide is established by an interplay between ionization from the Sun and from deep space, and the exponential decline of air density with altitude above the Earth's surface. The principal radiation components in this context are the galactic cosmic radiation and the UV and X-ray photons from the Sun. The cosmic radiation is the most energetic and serves to dominate the ionization and electrical conductivity at altitudes from 0 to 50 km. The cosmic radiation is also largely isotropic and so the conductivity structure of the lower atmosphere is spherically symmetrical. The UV radiation from the Sun is largely removed in causing ionization at higher altitudes – in the 'D' and 'E' regions of the ionosphere – and since this radiation is strongly anisotropic, the conductivity structure is endowed with a modest asymmetry between the daytime and the nighttime hemispheres. As a result, the electromagnetic waveguide departs slightly from spherical symmetry.

In treating the DC global circuit, we are concerned primarily with the spherically symmetric lowest region of the atmosphere, where small ions are the dominant charge carrier. Over the oceans, where the air is relatively free of aerosol particles, the altitude (z) dependence of the electrical conductivity can be approximated by the exponential function

$$\sigma(z) = \sigma_0 \exp(z/z_0) \quad [1]$$

where $\sigma_0 = 5 \times 10^{-14} \text{ S m}^{-1}$, and the e-folding scale height $z_0 = 5.0 \text{ km}$. The minimum atmospheric conductivity is found at the Earth's surface and contrasts markedly with conductivity values for the oceans and typical surface crustal material. This information establishes quantitatively the medium of the global circuit – a spherical capacitor with variable resistivity among good conductors.

Current sources for the DC global circuit are in principle any mechanism that separates positive from negative charge vertically between the conductive Earth and the upper atmosphere.

Such mechanisms include the vertical transport of electric space charge in the planetary boundary layer, the gravity-driven descent of selectively charged aerosol particles in the atmosphere, and the separation of electric charge by microphysical processes involving ice in showerclouds and thunderclouds. The Wilson hypothesis postulates the special subset of thunderstorms as the dominant current sources, or batteries, for the global circuit, though much evidence has appeared that showerclouds without lightning are also major contributors. The Wilson hypothesis establishes a firm link between the polarity of charge on the Earth and the polarity of thunderclouds, but does not account for the polarity of either entity. Today, it seems likely that this polarity is determined by some fundamental property of ice, still to be identified.

The behavior of current sources in a medium whose conductivity structure is exponential in the vertical has been examined mathematically. The solution for a point source in an exponential medium infinite in the vertical is for all current to flow upward toward higher conductivity. When horizontal conductor boundaries and the associated image sources are added, some current flows locally to Earth with the remaining flowing upward toward larger conductivity. Consistently with these theoretical calculations, observations over thunderstorms do show systematic upward current flow to higher altitudes, in line with the Wilson hypothesis. In a closed global circuit, the integrated upward current from globally distributed sources, approximately 1 kA, must ultimately return to Earth, as illustrated in Figure 2. On account of the spherical uniformity of conductivity structure, the current flow will also be spherically uniform in the resistive lower atmosphere. According to Ohm's law, this uniform integrated current density, J_0 , will set up a vertical electric field given by

$$E(z) = \frac{J_0}{\sigma(z)} = \frac{J_0}{\sigma_0 \exp(-z/z_0)} \quad [2]$$

giving an electric field at the Earth's surface of 40 V m^{-1} which declines exponentially with increasing altitude. The total voltage drop across the giant spherical capacitor will then be given as the line integral of this vertical electric field (where one-dimensional coordinates are used rather than spherical coordinates, as the vertical extent of the Earth-ionosphere cavity is small in comparison with the radius of the Earth, R_E):

$$V_1 = \int E(z) dz = \frac{J_0 z_0}{\sigma_0} \quad [3]$$

While the limits of field integration extend from the Earth's surface to infinity, the 5-km scale height for conductivity and electric field indicate that in three scale heights the field is reduced to 5% of its surface value and hence more than 95% of the voltage drop is achieved at 40 km altitude. The integrated potential difference between the Earth and the upper atmosphere is called 'ionospheric potential.'

The numerical evaluation of V_1 in the simplified treatment of the global circuit includes the experimentally determined current density in fair weather, J_0 ($2 \times 10^{-12} \text{ A m}^{-2}$), the conductivity scale height z_0 (5 km), and the (extrapolated) conductivity of air at the surface ($5 \times 10^{-14} \text{ S m}^{-1}$). The resulting V_1 value from eqn [3] is 200 kV, which is somewhat less than the value of actual measurements (mean value 250 kV). The primary reason for this discrepancy is the neglect

of the aerosol-laden planetary boundary layer, the shallow (~ 1000 m) zone near the surface in which the conductivity departs from the simple exponential form given earlier in eqn [1]. The local complications of the planetary boundary layer have been the major obstacle to the measurement of the global circuit from the Earth's surface. Measurements at sea, where the boundary layer is substantially less polluted, have shown records similar to the Carnegie curve on individual days, but even at sea problems can arise.

The steady-state distribution of electric space charge within the resistive lower atmosphere of the spherical capacitor may be determined from Poisson's equation,

$$\rho(z) = \epsilon_0 \frac{dE}{dz} = -\frac{\epsilon_0 J_0}{\sigma_0 z_0} \exp\left(\frac{-z}{z_0}\right) \quad [4]$$

where ϵ_0 is the permittivity of free space. According to these simple electrostatic predictions, positive space charge is distributed throughout the atmosphere, with maximum value in the lowest part of the atmosphere, as indicated schematically in Figure 2. An equal and opposite negative charge resides on the Earth's surface, with charge density per unit area given by

$$S = \epsilon_0 E(z = 0) = \frac{\epsilon_0 J_0}{\sigma_0} \quad [5]$$

and with total negative charge on the Earth

$$Q_{\text{tot}} = 4\pi R_E^2 S = \frac{4\pi R_E^2 \epsilon_0 J_0}{\sigma_0} = 2 \times 10^5 \text{ C} \quad [6]$$

Note that this charge is large in comparison with the charge transferred by single lightning discharges (~ 10 C), which as a consequence have no discernible effect on the steady-state V_1 values or the surface electric field. The capacitance of the giant spherical capacitor is, by definition,

$$C = \frac{Q_{\text{tot}}}{V_1} \quad [7]$$

whose value is approaching 1 F. The integrated resistance of the global circuit can also be computed analytically, again ignoring the contribution of the resistive and highly variable planetary boundary layer, which is most prevalent over land areas. This global resistance is most easily obtained directly from Ohm's law as

$$R = \frac{V_1}{I_{\text{tot}}} = \frac{V_1}{4\pi R_E^2 J_0} = 200 \Omega \quad [8]$$

The time required for the voltage across the giant capacitor to decay if all sources suddenly ceased is the RC relaxation time:

$$RC = (200 \Omega)(1 \text{ farad}) = 200 \text{ s} \quad [9]$$

Using typical parameters, this gives a relaxation time of 200 s or about 3 min. This time is somewhat longer if the effect of the resistive planetary boundary layer is included.

Schumann Resonances

The AC global circuit shares the same Earth-ionosphere medium as the DC global circuit but is a substantially richer and more complex phenomenon. Electromagnetic standing

waves within the Earth-ionosphere cavity, excited by lightning flashes worldwide, are known as Schumann resonances. The resonant frequencies are determined by the circumference of the natural waveguide and by the speed of light within the waveguide. The fundamental resonant frequency is 8 Hz.

The effective ionospheric height for the AC global circuit is systematically greater than for the DC circuit. The propagation of electromagnetic waves requires the displacement current to exceed conduction currents; the latter currents damp the waves. A meaningful estimate of waveguide height is found by equating the displacement current and the conduction current

$$J_D = J_C \quad [10]$$

$$\omega \epsilon_0 E = \sigma E \quad [11]$$

$$\omega \epsilon_0 = \sigma(z) \quad [12]$$

The height dependence of electrical conductivity is given by eqn [1], and so for a frequency of 8 Hz this condition can be solved for a height, which is approximately 50 km. This value is approximately 10 conductivity scale heights and hence is significantly greater than the height needed to achieve the ionospheric potential [3] of the DC global circuit.

The application of Maxwell's equations to a thin spherical waveguide (assumed uniform for simplicity of treatment) leads to the normal mode equations for the electric and magnetic fields resulting from a single vertical lightning discharge with frequency-dependent current moment $I dS(\omega)$, where I is the current in amperes and dS is the vertical extent of the current-carrying channel. The role of the ionosphere is treated with the complex eigenvalue ν , which is frequency dependent. The parameter a is the radius of the Earth and h is the height of the waveguide. The P_ν^0 and P_ν^1 are complex Legendre polynomials and their derivatives, respectively. The distance between the lightning source and an observer along a great circle path is given by θ .

$$E(\omega) = \frac{I(\omega) dS \nu(\nu+1) P_\nu^0(-\cos \theta)}{4R_E^2 \epsilon_0 \omega h \sin(\pi \nu)} \quad [13]$$

measured in $\text{V m}^{-1} \text{ Hz}^{-1}$

$$H(\omega) = \frac{I(\omega) dS P_\nu^1(-\cos \theta)}{4R_E h \sin(\pi \nu)} \quad [14]$$

measured in $\text{A m}^{-1} \text{ Hz}^{-1}$

These equations have been successfully merged with measured electromagnetic fields to construct global maps of extraordinarily energetic lightning flashes, whose fields dominate all other lightning on the planet for periods of several hundred milliseconds. Such maps strongly resemble the maps produced by satellite observations in Figure 4 in showing strong continental dominance.

The majority of lightning flashes are not sufficiently energetic to stand out above all other events, and the electromagnetic fields of this far larger population of ordinary flashes superimpose to produce the quasi-steady 'background' resonances. The phase information for the integrated activity is lost and the observations are normally documented as power spectra of electric and magnetic fields. Sample spectra, integrated for a complete 24-h period for three field components

Figure 4 Schumann resonance power spectra in the vertical electric (top panel) and two magnetic field components (middle and bottom panel), as measured in West Greenwich, Rhode Island, on 1 January 2000. The fundamental mode near 8 Hz is dominant in all spectra. Four to five higher order modes are also discernible.

(vertical electric, north–south magnetic, and east–west magnetic), are shown in **Figure 5**, where well-defined peaks at 8 Hz for the fundamental mode are seen as well as higher resonant frequencies at 14, 20, 26, and 32 Hz. The widths of the various spectral peaks are indicative of the quality factor Q of the Earth–ionosphere cavity. One definition of Q is

$$Q = \frac{f_0}{\Delta f} \quad [15]$$

where f_0 is the center frequency and Δf is the frequency interval between half-power points of the resonance curve. Dimensionless Q values are typically in the range of 3–8, indicating that the Schumann resonances are not sharply tuned owing to the lossy nature of the ionosphere.

The background Schumann resonances are more difficult to interpret for lightning source properties (location and intensity), because the sources are less localized than for single events and because lightning near the receiver can dominate the signal and mask more distant activity. Nevertheless, because of the overwhelming dominance of lightning in continental zones (**Figure 4**), even the sources for the background resonances exhibit considerable localization. A modified form of eqns [13] and [14] has been used to infer the

Figure 5 Global distribution of lightning based on (a) optical observations with the DMSP satellite at local midnight (Orville and Henderson, 1986), and (b) optical observations during both day and night with the Optical Transient Detector. Courtesy NASA Marshall Space Flight Center.

global vertical dipole moment change squared per unit time based on observations of the electric and magnetic power spectra. These measurements are broadly consistent with earlier estimates of 100 s^{-1} for the global lightning flash rate.

Comparative Response of the DC and AC Global Circuits

The first three modes of the electric field of the global circuit are illustrated within the Earth–ionosphere cavity in **Figure 6**. Mathematically speaking, the DC global circuit is the zeroth-order mode of Schumann resonances, the AC global circuit. On this basis, one might expect the ionospheric potential of the DC circuit and the global charge moment squared per unit time of the AC global circuit to be highly correlated on all timescales. While high-quality comparisons of simultaneous behavior are scarce, the available evidence does not support this prediction. A likely reason for different behavior lies with the sources, which drive the two global circuits, and the different meteorological origins of these sources. **Table 1** summarizes the principal source currents for the DC and AC global circuits. Charge transfer by point discharge current, by falling precipitation, and by lightning are all deemed important for the DC global circuit, whereas only lightning is believed to contribute substantially to Schumann resonances.

Figure 6 Illustrations of the behavior of the vertical electric field for the first three modes of the Earth–ionosphere cavity. The zeroth-order mode is the DC global circuit. Adapted from Wait, J.R., 1996. *Electromagnetic Waves in Stratified Media*, IEEE Press, Piscataway, NJ.

Table 1 Dominant current sources for the global circuit

DC circuit	AC circuit
Point discharge current	Lightning current
Precipitation current	
Lightning current	
Boundary layer convection	

Historically, the behavior of the diurnal variation of the DC global circuit shown in [Figure 3](#) is viewed as the cornerstone of atmospheric electricity and a critical test of the Wilson hypothesis that thunderstorms sustain the source currents. According to the simplified earlier development of ideas, a diurnal variation in integrated current J_0 will manifest itself as a diurnal variation in V_1 and in the surface electric field $E(z=0)$ on a global basis. As noted earlier, the phase agreement between the thunder day variations and the Carnegie curve is quite good, but the amplitude variation of the proxy lightning record is more than twice that of the Carnegie curve. Three major tropical storm regions are represented in the thunder day data in [Figure 3](#) as separate peaks but such clean distinction is not apparent in the Carnegie curve. These results strongly suggest that lightning is not the main contributor to the DC global circuit. Consistent with this conclusion is the experimental evidence that the local diurnal variation of point discharge current, rainfall, and rain current are all substantially smaller than the local diurnal variation of lightning. Since point discharge currents, rain currents, and boundary layer convective charge transport are present in weather systems other than thunderstorms, it would appear that a larger collection of weather elements than thunderstorms alone is needed to account for the modulations of the DC global circuit.

Further evidence for diverging behavior between the DC and AC global circuits comes from quantitative comparisons of the contributions from each of the three major tropical zones with the diurnal variation in UT ([Figure 3](#)). Africa is frequently the dominant lightning producer both in the classical thunder day analysis and in numerous observations of lightning from satellites in space ([Figure 4](#)). By contrast, the Carnegie curve peaks at 19.00 UT when the Americas are most active, suggesting that the Americas are the dominant tropical contributor to the DC global circuit.

The annual variation of the global circuit is more thoroughly documented for the AC component, because of numerous available observations of global lightning, and shows a maximum in Northern Hemisphere summer. The comparisons also indicate a similar result to that on the diurnal timescale: the annual variation of lightning (nearly a factor of two) is substantially larger than the annual variation of surface electric field and ionospheric potential.

Applications of the Global Circuit

A Monitor for Global Change

The verification and physical understanding of global change has become a topic of enduring interest worldwide. The connection between a currently increasing CO_2 concentration and an increasing mean global temperature is controversial and still unresolved. The global circuit provides a unique natural framework for monitoring global integrals: the collective current from electrified convection and the total lightning activity. The expectation that global circuit integrals are responsive to temperature is based on well-recognized local behavior. For example, lightning is more likely in the hot afternoon than during cool nights. At midlatitude locations, lightning is more frequent in the hot summer than in the cold winter. In the tropics, lightning is more frequent during warm

equinox than during cooler solstice. At all latitudes, lightning is more common over warmer land than over cooler ocean. In general, in the present climate, one finds greater cloud electrification and higher lightning flash rates in regions characterized by stronger conditional instability, larger CAPE (convective available potential energy), and larger updraft speeds. In the tropics, such regions are characterized by large wet-bulb potential temperature, a thermodynamic quantity representing both temperature and moisture.

With the aim of understanding global circuit response to temperature change, a general strategy in recent years has been to examine global circuit behavior on timescales for which the temperature variations and the underlying forcings are reasonably well established. Substantial correlations between global circuit behavior and the underlying global meteorology (which is often temperature related) have now been identified on the diurnal, the 5-day, the 25-day, the 30- to 60-day Madden-Julian oscillation, the semiannual, the annual, and the interannual (El Niño Southern Oscillation) timescales. The global circuit sensitivity to surface air temperature on these various timescales is generally in the range of 10–100% per $^{\circ}\text{C}$. For many of these studies, the determination of a quantitative sensitivity to temperature has been hindered by the poor sampling of temperature in regions dominated by deep convective activity (i.e., tropical South America and Africa).

The response of the global circuit to a long-term increase in temperature associated with global warming remains an open question. Measurements of the global circuit have been underway for only 50 years and very sporadically. The Schumann resonance records are substantially shorter. These records do not show significant upward trends. Results from a general circulation model point to an increase in lightning, but the key quantities for lightning in the models, like cloud buoyancy and convective scale updraft strength, are poorly resolved. If CAPE is invariant on the long timescale, the only change to be expected is the increase in moisture with temperature following the fundamental Clausius-Clapeyron relation. This dependence is approximately 6% per Kelvin and is substantially smaller than the global circuit sensitivity to temperature change documented on shorter timescales. Further work and longer records are required to discern a meaningful long-term change.

The DC global circuit also affords an opportunity to investigate changes in boundary layer pollution on a global basis. The strategy would be to distinguish variations in V_1 caused by source current from variations in V_1 caused by global circuit resistance. The latter quantity is influenced by the resistance of the planetary boundary layer, which is in turn influenced by the aerosol population that removes small ions and reduces the local electrical conductivity. Simultaneous measurements of the ionospheric potential V_1 and numerous single-station measurements of the air-earth current density would suffice to compute a global electrical resistance value (recall [eqn \[8\]](#)) whose changes could then be monitored. This experiment has not yet been performed, but the requisite observational methods have been established and verified.

Mesospheric Discharge Phenomena

Optical phenomena in the mesosphere high above large thunderstorms (mesoscale convective systems) have been

firmly documented within the last decade, and named sprites, elves, and trolls. All of these phenomena appear to be accompanied by a high-amplitude ‘ringing’ of the Schumann resonances by single-energetic cloud-to-ground lightnings. The application of the normal mode eqns [13] and [14] to these isolated transients enables the location and vertical charge moments to be extracted on the basis of ELF (extremely low frequency) global circuit measurements. Such observations appear to verify Wilson’s speculations in the 1920s that a sufficiently large dipole moment change by lightning in the lower atmosphere can cause a field increase in the upper atmosphere large enough for dielectric breakdown and ensuing optical emission. Global maps of event locations can be prepared on the basis of ELF measurements from a single location. Such maps are proxy maps for sprites.

Curiously, the great majority of flashes that cause upper atmospheric discharges are ground flashes with positive polarity, the opposite of the far more common negative ground flash that recharges the Earth negatively. Studies of the giant positive discharges with Schumann resonance methods have shown that they exhibit larger current and transfer greater amounts of charge than their negative counterparts. It is not known whether this asymmetry is related primarily to local meteorology and differences in the nature of the local charge reservoirs for the two lightning types, or whether a contribution arises from the fact that negative flashes are charging the DC global circuit and positive flashes are discharging it.

Diagnostic for the D Region of the Ionosphere

The upper conductive boundaries of both the DC and AC global circuits lie in the lowermost regions of the ionosphere, where the electron density is some four orders of magnitude smaller than its daytime maximum near 300-km altitude. Even large-aperture radars are insufficiently sensitive to detect and monitor the lower D region. Measurements *in situ* by rockets are limited in space and time. Schumann resonance methods may provide a useful global diagnostic for ionization in this region. The parameters of greatest interest are the Schumann resonance frequencies, determined by phase velocities of the resonant waves, and Q values, both of which depend on conductivity profiles that change with modulations in ionizing radiation. Recent results have shown systematic increases in the resonant modal frequencies over the recent solar cycle that are attributable primarily to ionization increases in the 80–90 km altitude range.

Conclusion

Renewed interest in the global electrical circuit within the last decade has spurred new methods for measurement, the initiation of dedicated monitoring programs, and a greatly improved understanding of the global circuit’s relationship with meteorology and ionospheric physics on many timescales.

The DC global circuit is difficult to measure on a continuous basis, but possesses a global invariant, ionospheric potential, that is well defined and quantitatively accessible. The Schumann resonances are relatively easy to measure on a continuous basis and are insensitive to the local variations in the planetary boundary layer, but the global invariant is more difficult to extract from single-station records. Coordinated measurements with both DC and AC aspects are most likely to bear the greatest fruit.

Ions in the Atmosphere

KL Aplin, University of Oxford, Oxford, UK

RG Harrison, The University of Reading, Reading, UK

Synopsis

Earth's atmosphere, like all planetary atmospheres, is constantly ionized by cosmic rays. Close to the surface, natural radioactivity is the dominant source of ionization. This article describes the generation and physical characteristics of atmospheric cluster-ions, including their size, composition, transport, and electrical properties, and gives an overview of relevant measurement technologies. The role of cluster-ions in weather and climate through modulating atmospheric particle formation and a range of other electrical effects is summarized. Nomenclature and categorization of atmospheric cluster-ions, and the properties of ions in the indoor environment are also briefly discussed.

Introduction to Atmospheric Ions

In Earth's atmosphere, an ion is a cluster of molecules carrying an overall charge, known as a *molecular cluster ion*. Such cluster ions, with dimensions of approximately 1 nm, have usually been referred to as *small ions*, and their motion in air constitutes a small electric current. *Large ions* (or Langevin ions), by comparison, are physically larger (tens to hundreds of nanometers) and consequently electrically less mobile. Usage of the term 'ion' to represent these molecular clusters originates from the early history of atmospheric electricity, which spans the discovery of the electron and the elucidation of the structure of matter. The distinction between large and small ions originates from distinguishing ions that could be accelerated by atmospheric electric fields (and therefore directly contribute to the conductivity of air), and those (the large ions) which were insufficiently electrically mobile to contribute to electrical conduction in air.

Particle Spectrum

Modern measurements have identified ions as part of the atmospheric aerosol spectrum. Aerosol particles span a wide range of sizes in the atmosphere, with dimensions from a few nanometers to tens of microns, and the smaller particles are more numerous. Large ions are effectively submicron aerosol particles, which have acquired electrical charges (Table 1). Many of the smaller aerosol particles are capable of acting as nuclei for trace gas condensation, depending on the supersaturation, but an important small fraction can act as cloud condensation nuclei (CCN).

Table 1 Typical properties of atmospheric particles and droplets

Particle	Radius (μm)	Mobility ($10^{-6} \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$)
Small ions	0.005–0.008	0.5–100
Large ions	0.008–0.03	0.05–0.5
Aerosol	0.003–30	
Cloud droplets	2–30	
Rain drops	30–3000	

Ion Formation

Small ions form by the interaction between energetic particles, from natural radioactivity and cosmic rays, with air molecules. The atomic ions and free electrons formed by this radiolysis are highly polarizing, and clustering ligands rapidly attach to them by hydrogen bonding. Large ions are formed by collisions between preexisting aerosol and small ions, which lead to the small ion becoming attached to the larger particle. The contribution of the small ion's mass to the combined particle is insignificant, but the attachment process transfers charge to the larger particle. Further collisions between small and large ions can occur, generating multiply charged large ions, or neutral particles if the combining ions have opposite polarities. Interactions between small and large ions occur from kinetics, and electrical forces only become significant for highly charged large ions. Collisions between aerosol and small ions serve to remove small ions: in air containing large quantities of aerosol the small ion content becomes correspondingly small. The removal of ions by aerosol is the basis for one type of domestic smoke alarm. This also means that, although the conductivity of air is principally due to its small ion content, the conductivity is inversely influenced by large ions and aerosol through their removal of small ions.

Chemical Composition

Atmospheric small ions consist of clusters of molecules collected around a singly charged ion. Clustering occurs within microseconds of ionization, and the ions have a lifetime of the order of a hundred seconds. Positive clusters take the chemical form $\text{I}^+(\text{X})_n$, where I^+ is a typical atmospheric species, for example, H_3O^+ , NO^+ , or NO_2^+ , and X is usually an atmospheric trace gas with high proton affinity, such as ammonia, pyridine, or water vapor. The rate of attachment and the ion species created depend on both the abundance and proton affinity of trace gases present. Similarly, negative ions can be represented as $\text{I}^-(\text{Y})_n$, where the ion could be O_2^- , CO_4^- , NH_3^- , or NO_2^- and the ligand is an atmospheric electronegative species such as SO_2 , HNO_3 , or water vapor; n is typically between 4 and 10. The chemical difference between the species in the positive and negative ions leads to some physical asymmetries in the ion

properties, so the negative ions tend to have fewer molecules clustered around them, and as a result are observed to be about 20% more mobile than the positive ions.

Electric Charge

Small ions are singly charged, and respond to electric fields. The *electrical mobility* μ describes the speed that a molecular ion will attain in an electric field. It is the ratio of the magnitude of the electric field to the ion's *drift velocity*. (The electrostatic forces acting on the particle are assumed to balance the drag forces, so there is no net acceleration.) Small ions have a mobility of around $10^{-4} \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$, and are more strongly influenced by electric fields than larger aerosol particles. The current flowing through the air is almost entirely due to these small ions, and the total *conductivity* σ can be written as

$$\sigma = e(n_+\mu_+ + n_-\mu_-) \quad [1]$$

where there are, respectively, number concentrations n_+ and n_- of positive and negative ions, with mean mobilities μ_+ and μ_- and e is the magnitude of the electronic charge.

Ion Transport

With typical vertical atmospheric electrical fields in fair weather of 100 V m^{-1} , small ions will typically migrate under electrical forces at about 1 cm s^{-1} or less. However, the electrical migration is able to occur in regions where there is little dynamical motion, in meteorological terms, and consequently clean air will always have fresh ions introduced into it either by electrical migration or *in situ* ionization. In contrast, large ions and atmospheric aerosol have negligible electrical acceleration, and their primary motion is due to advective transport arising from dynamical processes. The charge transported may therefore be ionic, or particulate (large ions), and the partitioning of the atmospheric *space charge* (the net amount of charge per unit volume) determines whether air motion or electric fields dominate.

Ions in the Global Atmospheric Electric Circuit

The terrestrial atmospheric electrical circuit exchanges charge between the planetary surface and the upper atmosphere, and is maintained by a combination of charge separation in thunderstorms and vertical ionic conduction currents in the larger fair weather regions. The conduction currents can only flow because there are charged molecular clusters (ions) present, which are sufficiently mobile to be accelerated by the small electric fields present in the atmosphere. Consequently, ions have an important part to play in maintaining the global atmospheric electric circuit. The charge-generating effect of thunderstorms and shower clouds leads to a small conduction current throughout fair weather regions of current density about 2 pA m^{-2} . The *conduction current density* J is defined by

$$J = -\sigma E \quad [2]$$

where σ is the conductivity and E the vertical electric field. If integrated across the surface of the whole planet, the ionic conduction current totals about 2000 A, [Figure 1](#).

Ion Balance Equation

The time variation of atmospheric ion concentrations can be expressed as a simplified equation, the ion balance equation, in which rates of ion formation and removal are considered separately.

Source Term

Formation of ions is, as mentioned above, essentially due to radiolysis of air molecules. There are three principal sources near the continental surface: radon isotopes, cosmic rays, and terrestrial gamma radiation, and the partitioning between the sources varies vertically. Close to the surface, ionization from turbulent transport of radon and other radioactive isotopes is important, together with gamma radiation emitted by isotopes below the surface. Cosmic rays are always present, comprising about 20% of the ionization at the surface. The cosmic ray contribution to ionization increases with increasing height in the atmosphere and dominates above the planetary boundary layer, as depicted in [Figure 1](#). The rate of production of ion pairs per unit volume is usually written as q , and this quantity shows considerable temporal and spatial variability because of geological variations, or, over the oceans, solar activity. The increasing fractional contribution of cosmic ray ionization with height has already been mentioned, but the temporal variations in q at the surface are also substantial due to the effects of turbulence and the transient production of ions. q has a frequently quoted surface value of $10 \text{ ion pairs cm}^{-3} \text{ s}^{-1}$, which is a long-term mean. On timescales of seconds, there can be significant departures from this value. In the middle and upper troposphere, the cosmic contribution to q dominates.

Bipolar Ion Equations

The ion balance equations describing production, recombination, and attachment are

$$\frac{dn_+}{dt} = q - \alpha n_+ n_- - n_+ \beta_+ Z \quad [3]$$

$$\frac{dn_-}{dt} = q - \alpha n_+ n_- - n_- \beta_- Z \quad [4]$$

in which the rate of change of ion concentration is determined by an ion source term q , and the two loss terms described above. Ion pairs are produced at a rate q per unit volume. If there are number concentrations n_+ and n_- of positive and negative ions, respectively, then the rate at which they recombine is proportional to $n_+ n_-$, with a constant of proportionality α , also known as the *ion-ion recombination coefficient* and typically assumed to be $1.6 \times 10^{-6} \text{ cm}^3 \text{ s}^{-1}$. Recombination is the principal loss mechanism of ions in clean, aerosol-free air. In more polluted air, the rate of ion loss by attachment is given by $n\beta Z$, where β_+ and β_- are the appropriate ion-aerosol attachment coefficients and Z the aerosol number concentration. In these equations, a considerable simplification has been made in assuming that it is possible to regard the aerosol as *monodisperse* (i.e., having a single particle size) so a single value of Z is appropriate. The attachment coefficient varies with

Figure 1 The role of ions in the atmospheric electrical system. Major sources of atmospheric ions are cosmic rays, and, in the boundary layer, radon isotopes diffusing from the surface, with a small contribution from point discharge currents and anthropogenic corona ions. The ions formed may become attached to atmospheric aerosol particles, or to water droplets in clouds. The remaining ions are accelerated by atmospheric electric fields, originating from charge separation occurring in thunderstorms, to form the conduction current with density J_z . Diagram kindly provided by Dr Nicoll, K.A. (Department of Meteorology, University of Reading).

aerosol radius, therefore βZ is in fact more accurately determined for atmospheric particles as an integral evaluated across the aerosol size distribution. There are many theoretical approaches to the problem of calculating β , which depend on the aerosol particle size considered, but β is typically $5 \times 10^{-5} \text{ cm}^3 \text{ s}^{-1}$ for aerosol particles with the radii most prevalent by number ($0.2 \text{ } \mu\text{m}$) in lower regions of the atmosphere.

Time-Dependent Solution

The ion balance equation can be simplified by neglecting the ion sign (i.e., $n_+ \approx n_- = n$), so that the ion-aerosol equation can be written as

$$\frac{dn}{dt} = q - \alpha n^2 - n\beta Z \quad [5]$$

Integrating this equation gives the ion concentration n as a function of time t . This time-dependent solution is

$$n(t) = \frac{[(\beta^2 Z^2 + 4\alpha q)^{1/2} - \beta Z]}{2\alpha} \left[\frac{(1 - e^{-(\beta^2 Z^2 + 4\alpha q)^{1/2} t})}{(1 + e^{-(\beta^2 Z^2 + 4\alpha q)^{1/2} t})} \right] \quad [6]$$

showing that firstly, if the ion-pair production rate q is uniform and the removal rates are also steady, the ion concentration tends to a steady value for large values of t . Secondly, the equation can be simplified according to the situations in which attachment or recombination dominates as the removal mechanisms, according to whether αn^2 or $n\beta Z$ is the bigger term. In moderately polluted air, these two terms are roughly comparable, and therefore all the terms in eqn [6] have to be evaluated.

In clean air, when ion loss can be assumed to be solely by recombination, eqn [6] reduces to

$$n(t) = \left[\frac{q}{\alpha} \right]^{1/2} \left[\frac{(1 - e^{-2(\alpha q)^{1/2} t})}{(1 + e^{-2(\alpha q)^{1/2} t})} \right] \quad [7]$$

and the concentration after a long time has elapsed is given by $n_\infty = (q/\alpha)^{1/2}$. Inserting typical atmospheric values of $q \approx 10 \text{ ion pairs cm}^{-3} \text{ s}^{-1}$ and $\alpha = 1.6 \times 10^{-6} \text{ cm}^3 \text{ s}^{-1}$ gives $n_\infty = 2500 \text{ ion pairs cm}^{-3}$. Typical values of small ion concentrations observed in mountain air are about 500 ions cm^{-3} of each sign, suggesting that attachment processes are almost always a further factor acting to modulate natural ion concentrations. There is one other factor which influences measured ion concentrations: adjacent to the surface, when the atmosphere is stable, the planet's negative charge causes an

increase of positive ions and a depletion of negative ions. This is known as the *electrode effect*.

Ions and Health

Indoor atmospheres are frequently deficient in small ions, and asymmetries in ion removal due to charged surfaces on furnishings lead to asymmetries in the remaining ion concentrations. It has been suggested that this may be the cause of some health problems, but this work appears inconclusive. Ionizers are widely used domestically to produce additional ions (generally negative ions, by corona), to replenish concentrations in indoor environments, but it is difficult for this not to affect the charging of aerosols and therefore their removal. Both positive and negative ions are readily produced in atmospheric air, therefore if there is any conceivable support for the anecdotal effect on health it is likely to be a result of the asymmetry in their concentrations. However, there is some experimental evidence that negative ions have bactericidal effects.

Ion Measurement

Atmospheric ions can be measured by exploitation of their electrical properties, for example, their migration toward an opposite charge in an electric field. The simplest way of counting ions is to apply an electric field, for example, by blowing air between two metallic plates or in a conducting cylinder with a central electrode. If one of the plates is grounded, and the electric field sufficiently strong to ensure all the unipolar ions are collected on the other electrode, then a current can be measured which is proportional to the concentration of air ions. As small ions are known to be singly charged, then the number of ions can easily be calculated.

Gerdien Condenser

If only a fixed fraction of the ions contributes to the ion current, then the electrical conductivity of the air can be measured. Gerdien, of Göttingen, first developed a method to measure air conductivity in 1905, which uses a cylindrical condenser, with a voltage applied between two cylindrical electrodes (Figure 2).

Ions are sucked into the cylinder with a fan, and those of the same sign as the polarizing voltage are repelled by the outer electrode, and move in the electric field to meet the inner electrode, where they cause a small current. In Gerdien's original configuration, the cylindrical capacitor was charged up to a fixed voltage, and the subsequent rate of decay depends on the concentration of air ions. If the time constant of the decay is τ , then the conductivity is given by

$$\sigma = \frac{\epsilon_0}{\tau} \quad [8]$$

An alternative technique, which was introduced later, was to earth the central electrode via a sensitive ammeter and measure the ion current. Typical currents in the large instruments of the early twentieth century were about 10^{-12} A, but in modern, miniaturized Gerdien condensers, sensitive electrometry can detect currents down to 10^{-15} A, giving resolution of about 20 ions cm^{-3} . Unipolar conductivity $\sigma_{\pm}$ is given by

$$\sigma_{\pm} = \frac{i\epsilon_0}{CV_{\pm}} \quad [9]$$

where i is the current, C is the capacitance, and V is the voltage across the electrodes. This relationship is valid for measuring conductivity, as long as the output current is proportional to the bias voltage, which indicates that a fixed fraction of air ions are collected by the central electrode. If the current is not linearly related to the voltage, then all the atmospheric ions are collected, and the instrument is operating as an ion counter. The method of current measurement described above is commonly deployed due to its simplicity and high time resolution, but the alternative voltage decay technique remains useful for calibration as it only requires relative voltage measurements rather than sensitive current measurements.

Mobility Spectrometry

In an aspirated cylindrical capacitor, the fraction of ions contributing to the measurement can be varied by changing the magnitude of the electrical field or the dimensions of the capacitor. This affects the maximum mobility (or minimum size) of ion that can pass through the instrument without being drawn to the central electrode and contributing to the current. A *critical mobility* μ_c , the minimum mobility of ion contributing to the conduction current, can be defined. If L is the length of the tube, a and b the radii of the outer and inner

Figure 2 Schematic of a Gerdien condenser for measuring atmospheric ions.

electrodes, u the air speed, and V the voltage across the tube, then μ_c is given by

$$\mu_c = \frac{(a^2 - b^2) \ln\left(\frac{a}{b}\right) u}{2VL} \quad [10]$$

Varying the voltage across the electrodes, or the flow rate through the instrument, therefore provides a way to study the abundance of ions of different sizes. If current measurements are made as different voltages are swept across the capacitor, ion concentration n can be estimated from the conductivity, and the critical mobility using the equation below.

$$n = \frac{\sigma}{e\mu_c} \quad [11]$$

Ion *mobility spectra*, which are important for observing the behavior of ions and their evolution, can be resolved with equipment based on this relatively simple principle.

Modern Implementations of Ion Spectrometry

The approach of using a cylindrical capacitor to measure ions is by no means new. However, present day electronics, data processing and materials technology make these sensitive measurements more straightforward than in the past, and there are now many types of mobility spectrometers and analyzers available. Modern instruments employ sophisticated engineering to ensure smooth airflow, reducing random collisional currents, and complex algorithms for mobility retrieval, but they are almost all based on the simple principles described above. Some mass spectra of ambient atmospheric ions have been measured, but this method is complicated by the need for a vacuum inside the mass spectrometer. Mobility-based techniques are usually considered most appropriate for obtaining detailed measurements of atmospheric ion composition.

Ions and Climate

Direct Condensation onto Ions

It has long been assumed that atmospheric ions have little relevance to the climate system, as they have no direct role in cloud formation. It is possible to demonstrate theoretically that condensation on ions cannot occur unless the air is highly supersaturated with water vapor, at levels vastly greater than the few percent observed in atmospheric air. The cloud chamber invented by C.T.R. Wilson is able to visualize the tracks of subatomic particles by the clouds forming on the ions produced only because the supersaturation it generates is typically 400%. Such supersaturation levels are not found in the atmosphere, therefore cloud formation by the direct nucleation of water clouds on ions is not expected to occur.

Proposed Mechanisms for Electrical Influences on Climate

Recent work has identified a greater possible significance for small ions within the climate system, because they are able to assist the formation of ultrafine aerosol particles, some of which may subsequently be able to act as CCN. Numerous modeling studies have indicated the theoretical likelihood of the growth of ions from particles. Laboratory experiments have shown that particles can grow from ions in air, in the presence of a range of radioactive sources and, recently, in beams of subatomic particles that more realistically simulate cosmic ray ionization. There are now many sets of atmospheric observations of small ions growing into intermediate ions and onto small aerosol particles, via a range of charge-enhanced nucleation pathways, referred to as 'ion-induced' or 'ion-mediated' nucleation. Nucleation enhanced by atmospheric ions has been observed both in the boundary layer and in the free troposphere, but it only makes a small contribution to the total background ultrafine aerosol particle concentration. Ions appear to contribute most to aerosol formation in clean locations with low background aerosol concentrations, such as the free troposphere, but it is not known if these new aerosol particles grow to sizes that influence solar or terrestrial radiation. At the moment there are no observations of CCN growing from ions in the atmosphere, and modeling studies indicate that the radiative effect from ion nucleation is negligible. However, there is evidence for a host of additional small effects that could link atmospheric ionization to climate. These include the modification of droplet charges (and therefore potentially their activation) at the base of clouds, charge-related scavenging and coagulation, and direct absorption of infrared radiation by the bending and stretching of hydrogen bonds inside atmospheric cluster ions.

Introduction

This article outlines the current understanding of lightning from tropospheric clouds. It begins with a brief history of research in this area and a summary of the tools used in the present-day studies. It then presents a short description of a lightning flash and discusses the major physical processes that lead to the production of lightning. This discussion provides the basis for the next topics: the links between lightning and other meteorological parameters, and the climatology of lightning.

Background

History of Lightning Research

Lightning is arguably the most dramatic naturally occurring atmospheric phenomenon, but the first understanding of its electrical nature came with Benjamin Franklin's famous experiments in the 1750s. These were followed by rapid advances in the theory of electromagnetic phenomena, with practical advances in lightning protection devices. In the 1920s C.T.R. Wilson suggested the role of thunderstorms in the atmospheric electrical system. In the 1950s and 1960s, as the field of cloud physics came into its own, the microphysical processes involved in thunderstorm electrification were widely studied, if not explained. Improvements in remote sensing of the relevant variables have further advanced our understanding of lightning as an atmospheric phenomenon, and lightning observations now provide information on cloud and atmospheric processes that complement traditional meteorological measurements.

Data and Models

Our understanding of lightning is derived from data from many sources. *In-situ* field mills, current meters, and induction rings mounted on meteorological balloons and/or aircraft yield small-scale information on in-cloud electric fields and charge distributions. Surface sensors located beneath storms and/or on mobile laboratories record electric field changes and currents associated with lightning along with colocated cloud physical variables. Sophisticated instruments measuring various components of the radiation associated with lightning can pinpoint the in-cloud locations of lightning strokes, and follow the lightning channel trajectories. Finally, lightning can be detected and its location mapped from great distances by optical detectors placed on space-based platforms and by detection at the surface of low-frequency electromagnetic signals propagating in the global waveguide.

These data can be used in numerical thunderstorm models of varying complexity to simulate the evolution of cloud and electrical properties over a cloud life cycle. These provide useful

means for testing new ideas, although at present incorporation of electrical phenomena in models requires semiempirical parameterizations.

Lightning: the Process

Lightning is an electrical discharge; i.e., a rapid redistribution of electrical charge within thunderclouds or between a cloud and its surroundings. IC, or intra-cloud lightning, is a discharge between two points in the same cloud; C–G, or cloud-to-ground lightning, transfers charge between a point in cloud and a point on the ground below. (Inter-cloud lightning, connecting points in different clouds, will not be treated here.)

A lightning flash consists of several components. In C–G flashes (which are those most widely and closely studied) a low-current (~ 1 kA), low-luminosity channel is initiated in the cloud. The channel is a fully ionized plasma tube several centimeters in diameter. Joule heating by electrical currents in the plasma raises the channel temperature to above 20 000 K. The heated gas expands, giving rise to shock waves producing the sound called thunder. The current carried by the channel discharges tens of millions of volts. The high temperatures inside the channel favor certain chemical reactions of atmospheric significance; in particular, the production of NO_x , treated elsewhere in this encyclopedia (*see Stratospheric Chemistry Topics: Reactive Nitrogen* (NO_x and NO_y)).

This first channel propagates downward in discrete steps 2–50 m in length separated by pauses of ~ 50 μs , and is commonly referred to as a stepped leader. This is followed by a return stroke (i.e., a return current) from ground to cloud. There may be several leader–return-stroke pairs but the time between strokes is usually too short for our eyes to resolve and thus what we call a lightning flash usually consists of several individual strokes. The return stroke is the brightest phase of the flash with typical peak currents ~ 40 kA; the average total current is several amps. **Figure 1** shows a sequence of strokes recorded on film.

The entire discharge lasts about 0.1 s. C–G flashes typically lower 20–30 °C to ground but values in excess of 200 °C have been recorded.

The high temperature inside the channel increases the pressure inside it and gives rise to a shock wave that expands into the surrounding air. Air resistance damps the wave and the pressure of the disturbance decreases rapidly, so that the far field effect is that of sound waves, or thunder.

Thunderstorms and Lightning

To understand the electrification of thunderstorms we review the electrical context in which they develop.

Figure 1 Lightning flash photographed with a streak camera. The camera moves during the lightning flash, enabling the resolution of a number of individual strokes. The Global Circuit

The surface of the Earth behaves like a negatively charged conductor. This conductor and the electrosphere (a region of net positive charge whose base is around 65 km altitude) constitute the 'plates' of a concentric spherical condenser. There is a fairly constant, spatially uniform fair-weather electric field in the atmosphere between the plates: $E_{\text{fair}} \approx 100 \text{ V m}^{-1}$ at the Earth's surface. This field is associated with a fair weather current of positive charge to the ground: $J_{\text{fair}} \approx 2 \times 10^{-12} \text{ A m}^{-2}$. Without 'batteries' the current would discharge the field in a few minutes. The major batteries, or generators, are thunderstorms, which deposit predominantly negative charge on the Earth's surface through lightning and precipitation. Thus lightning at any point perturbs the local electric charge distribution and the electromagnetic waves travelling in the global waveguide.

Thunderstorm Electrification

The electrical conductivity inside a cloud is much lower than that in the free air, since ions become attached to the hydrometeors. Thus insertion of a completely passive cloud into the fair-weather field results in the attachment of ions from the environment on hydrometeors at the cloud edges. As these move, the electric field distribution in the cloud changes. Fields up to $100\text{--}1000 \text{ V m}^{-1}$ are often found in "nonelectrified" clouds. In thunderstorms, on the other hand, internal charging mechanisms produce electric fields of up to 100 kV m^{-1} .

The information we have on in-cloud charge distributions is very limited, and we know only some general features, shown schematically in an idealized isolated convective thunderstorm in **Figure 2**. In simple storms like this one, a vertical dipolar or

Figure 2 Schematic picture of an idealized thunderstorm, showing the ascent of hydrometeors (round circles) in the updraft (velocity w) and sedimentation of the larger particles, which collide with smaller ones below. Rebounding collisions between hail particles and small ice crystals result in charge transfer between them. Gravitational separation of the lighter (positively charged) ice particles and the negatively charged graupel (i.e., soft hail) particles leads to the electric charge distribution shown. This precipitation-based charging is thought to dominate early thunderstorm electrification. Reproduced with permission from Schroeder et al. (2000) *How Does Lightning Initiate and What Controls Lightning Frequency?* PhD thesis, University of Washington.

tripolar charge distribution develops as the cloud grows, with typical charges $Q \approx 10\text{--}100\text{C}$ in each center at maximum, carried by the cloud water and ice particles. The positive charge is distributed in a diffuse region aloft; typically, the charge density in this region is several C km^{-3} . The negative charge center can be more compact, and is always located in the part of a cloud (called the 'charging zone') in which the temperature lies between -10°C and about -20 to -25°C . This is the only region inside clouds in which vapor-grown ice, supercooled water, and hail particles coexist. There are often other important pockets of charge, including a secondary positive charge center; these become larger and more complex as the cloud ages.

The fact that the negative charge center is confined in temperature suggests that microphysical interactions control the electrical charge distributions in this type of storm, although dynamic processes (transport in updrafts and downdrafts and turbulent motions) are also important. The major microphysical charging mechanism in convective storms appears to be charge separation between colliding ice particles.

Laboratory studies show that electric charge is separated during rebounding collisions between ice particles, so that the rebounding particles carry equal and opposite charge. The sign and magnitude of the charge are reproducible functions of temperature, particle types and sizes, and the cloud water content and distribution. At temperatures above a 'reversal' threshold, around -15°C , the hail generally receives positive charge, and at lower temperatures it receives negative charge during a collision. Typically the charge separated is around 10^{-14}C per collision when one of the partners is hail; far more charge is separated when both are hail and less when both are vapor-grown ice crystals. In general, the large (precipitating) hail particles receive net negative charge as they fall through the cloud of smaller ice crystals. Subsequently, gravitational separation of the large, negatively charged precipitation particles and the lighter, positively charged ice crystals constitutes a 'generator current' $J_{\text{gen}} \approx 0.1 \text{ A km}^{-2}$.

The collision-based process is the most important, but not the only one responsible for creating the observed in-cloud charge distributions. Other processes become more important as electrification proceeds; for example, cloud particles in the existing electric field become charged inductively; melting appears to be associated with charging in stratiform clouds; ions become attached to aerosol particles and cloud particles near cloud edges; finally, motions of charged particles redistribute them throughout the cloud system.

This inhomogeneous electric charge distribution produced by these processes is associated with an electric field. The field grows as the cloud develops and eventually conditions are met in which lightning is triggered. The first flash is typically initiated just above the lower, negative charge center and the first lightning is usually IC. The lightning flash transfers charge between the upper, positive charge center and points below. The net charge density aloft is thereby decreased and positive charge builds up somewhat below the negative charge center. Continued IC lightning as the convective cell reaches full vigor continues this charge redistribution process. At some point the electric field between the lower charge centers and ground becomes strong enough to trigger C-G flashes.

This classical picture does not describe all thunderstorms. Recent measurements (for example, those made during the

Severe Thunderstorm Electrification and Precipitation Study (STEPS) project in 2000) reveal that the charge structure in clouds is often inverted, with negative charge aloft. The exact mechanisms for this inversion are not known. Moreover, in complex cloud systems containing large stratiform regions and/or multicellular structures the charge distribution can be highly three-dimensional and complex.

Most C-G flashes from convective storms carry negative charge to ground, indicating that the in-cloud point of origin of the flash is associated with a negative charge pocket, but in midlatitude storms around 10% deposit positive charge to ground. Positive flashes tend to be associated with low precipitation regions in mesoscale storm systems, and they are often very intense. In general, reversed lightning polarity results from (1) wind shear, displacing the upper positive charge so that it overlies cloudfree air and is electrically coupled to ground; (2) inverted charge structure in cloud, possibly due to charging at temperatures higher than the reversal temperature; and (3) absence of large concentrated pockets of negative charge.

Microphysical Processes Leading to Lightning Production

In order to make further progress in understanding lightning generation we must solve two outstanding puzzles; namely, (1) what is the mechanism for the charge transfer between colliding ice particles, and (2) how is lightning initiated? In this section we briefly discuss our current understanding of these processes and the hypotheses now being tested to explain them.

Charge Transfer via Ice-Ice Collisions

The mechanism by which the rebounding ice particles become charged remains somewhat unclear. Both sign and magnitude of the charge depend on the rate of growth of the ice particle from the vapor. The charge transfer appears to be due to the fact that positive water ions in ice have much higher mobilities than do negative ions. Ions are created at high rates near the ice surface, and the positive ions migrate inside, so that the growth creates net negative charge at the ice-vapor interface. During a collision, material from the two particles is mixed and net negative charge is transferred to the particle with the slower growth rate. The various characteristics of the hail – i.e., its smoothness or roughness, the density of grain boundaries and dislocations, and the chemical composition of the frozen water – all modify the charge transfer.

Lightning Initiation

Lightning initiation is thought to involve the following stages. (1) The in-cloud electric fields intensify via microphysical and dynamic processes. (2) Free electrons in some region of the field begin to accelerate, creating more electrons via ionization, in so-called electron avalanches. If these continue they result in propagating corona streamers, or small-scale currents. (3) Heating associated with the propagation of high electric current through and beyond the region of very high local fields produces the hot, completely ionized lightning channel, or leader.

This process is known as ‘dielectric breakdown’. In the laboratory, dielectric breakdown can occur only if the ambient electric field reaches a (pressure-dependent) threshold value, denoted $E_{th}(p)$. At surface pressure (1000 hPa) $E_{th} \approx 2600 \text{ kV m}^{-1}$. This value, and the physics of breakdown in the laboratory context, are well understood. However, measured electric fields inside thunderclouds never reach the threshold value and are usually more than an order of magnitude less than this value.

Two classes of hypotheses are typically invoked to resolve this puzzle. While both involve acceleration of an initial electron and subsequent production of electron avalanches, everything else about the two mechanisms is different. The first is the ‘conventional breakdown’ hypothesis, which operates on very small spatial scales. It is based on the fact that in the vicinity of conducting hydrometeors the electric field magnitude can reach the breakdown threshold value. According to this lightning initiation hypothesis, free electrons near cloud ice and water particles are accelerated by the local field and can produce local streamers.

The second class of triggering mechanism hypotheses depends on the fact that in-cloud electric fields are fairly large, even if not of breakdown magnitude, over several kilometers. An electron moving in such a field is accelerated by the field and decelerated by its interactions with neutral molecules. If the electric field magnitude is sufficiently great, it can compensate for the deceleration. The balancing electric field is called the ‘breakeven’ field; $E_{be}(p) [\text{kV m}^{-1}] \approx 200p [\text{atm}]$, much smaller than the breakdown threshold field.

The ‘runaway breakdown’ hypothesis of lightning initiation suggests that if E_{be} is exceeded, even if slightly, over sufficient distance, then high-energy electrons (resulting from cosmic ray showers or atmospheric radioactivity, or short-lived, small-scale intense electric fields) travelling in the field can create sufficient daughter electrons by ionization to initiate a leader, or ionized channel. The more the field exceeds the breakeven value the shorter the distance needed to create the leader. Measured electric fields in clouds are generally much smaller than the breakeven field, and just reach it or barely exceed it immediately prior to a lightning stroke, lending credence to the runaway breakdown hypothesis.

Neither the conventional nor the runaway mechanisms are completely satisfactory; neither can explain all the observations. Unfortunately, balloon measurements cannot solve the lightning initiation puzzle because they are Lagrangian in nature, they sample very small volumes of cloud, and their spatial and temporal resolution is too coarse. Therefore considerable effort will have to be devoted to interpretation of complementary measurements in order to clarify the nature of the lightning trigger(s).

Lightning and Cloud Properties

Although much remains to be learned about lightning generation, we can examine some basic relationships linking lightning frequency $F [\text{s}^{-1}]$ to other important parameters. A simple dimensional argument illustrates the important links. F is a function of the charge generation rate, $\dot{\rho}_Q$, the depth H of the electrically active region and the threshold field for producing

lightning (which we assume here is a function of E_{be}). The charge-generating current density $J_{gen} \propto \dot{\rho}_Q H$.

Therefore

$$F \propto \frac{\dot{\rho}_Q H}{E_{be}} \quad [1]$$

Flash Rate and Radar Reflectivity in Charging Zone

For simplicity we neglect all contributions to $\dot{\rho}_Q$ except that due to collisions between hail particles and vapor grown crystals. Consider a situation in which $N_{hail} [\text{m}^{-3}]$ hail particles of diameter D_{hail} collide with N_{ice} vapor-grown ice particles of diameter d_{ice} . The laboratory charging results can be parameterized in terms of these variables, leading to an expression of the form

$$\dot{\rho}_Q \propto N_{hail} D_{hail}^6 N_{ice} d_{ice}^3 \quad [2]$$

$$\approx Z M_{ice} \quad [3]$$

where Z is the radar backscatter and M_{ice} the mass of vapor-grown ice in the region of the collisions. Thus, we can write

$$F \propto \frac{Z M_{ice} H}{E_{be}} \quad [4]$$

Therefore we expect the measured lightning frequency to increase with radar reflectivity (i.e., the large hail concentration) and with the mass of vapor grown ice. Both of these predictions have been borne out in preliminary analyses of lightning frequency vs. radar reflectivity and 85 GHz signal from thunderstorms. As a rule of thumb, a minimum radar reflectivity of around $Z = 40 \text{ dBZ}$ for temperatures about -7°C seems to be required for rapid electrification.

Flash Rate and Updraft Velocity

We can rewrite eqn [4] to relate F to updraft velocity in the charging zone. The fall velocity of the hail particles is very roughly proportional to the hail particle diameter. Therefore, if we assume that most of the collisions take place at the balance point, where the fall velocity of the hail particles is equal to the updraft velocity w , then

$$\dot{\rho}_Q \propto w^6 M_{ice} \quad [5]$$

Thus

$$F \propto \frac{w^6 M_{ice} H}{E_{th}} \quad [6]$$

Since updraft velocity in the mixed-phase zone is of importance in weather prediction, the strong dependence of lightning on this factor may provide a useful remote indicator of storm strength. More careful studies show that as a general rule the very existence of lightning implies vertical velocities of at least $7\text{--}8 \text{ m s}^{-1}$ in the charging zone. Updraft velocities are often tied to buoyancy, or CAPE (convective available potential energy), so that it is not surprising that observations tie F to CAPE in regions where sounding shape is not highly variable, such as over oceans; however, this relationship is regional over land and attempts to identify a single CAPE ‘threshold’ with the onset of lightning have not been very fruitful.

Flash Rate and Vertical Water Fluxes

It has long been hoped that, because of the role of hail in generating lightning, reliable and useful relationships could be found by which lightning frequency could be used as a surrogate for precipitation at the ground. Unfortunately, although it is possible to derive dimensional relationships between flash rate and in-cloud hail concentrations (see eqn [3]), universal quantitative relationships of sufficient accuracy for use in prediction are far from our reach. Many high precipitation storms produce no lightning at all (particularly if most of the precipitation comes from warm cloud processes), and the complex processes involved in producing precipitation (particularly precipitation at the ground, where predictions are most needed) are so variable on small spatial and temporal scales that precipitation cannot be accurately predicted from simple macroscopic measures like lightning frequency. Estimates of precipitation 'yield' γ for example, range from $10^7 \leq \gamma \leq 10^{10} [\text{kgH}_2\text{O flash}^{-1}]$ in one given location.

Since lightning frequency increases with increasing rate of supply of water to the charging zone and upward flux of small ice particles, lightning can be used in certain predictive schemes. Remote sensing of lightning has been successfully incorporated into predictions of hurricane landfall time and location, and more such applications are likely to follow. On larger scales, flash rate can also be considered a surrogate for the rate of water lofting to the upper troposphere in convective towers. A simple argument suggests that globally around $M_{\text{ice}} \approx 10^6 [\text{kg ice flash}^{-1}]$ is lofted to the upper troposphere. At present, attempts to make more quantitative estimates of regional condensate lofting from lightning observations have proved frustrating because the relationship is highly variable, but global lightning activity as inferred from ELF (extremely low-frequency) waves in the global circuit appears to be strongly correlated with tropical water lofting.

Lightning and Atmospheric Aerosols

Forest fires and urban pollution have been shown to produce anomalies in C–G lightning flash rate, lightning intensity (peak current, and/or radiance) and in the sign of the charge brought to ground by lightning. These intriguing observations might be

due to modifications of the hydrometeor populations by variations in the distributions of aerosol particles, to modification of the soundings by anomalous surface heating, to chemical modifications of the charge transfer process or to some combination of these.

Lightning Climatology

The advent of routine lightning monitoring programs from satellites and important advances in ground sensing capability have allowed great advances in our understanding of the distribution and frequency of lightning. Here we present an overview of lightning climatology.

The global, diurnal average C–G flashrate is $\bar{F}_{\text{C-G}} \approx 12\text{--}16 \text{ s}^{-1}$; $F_{\text{max}} \approx 55 \text{ s}^{-1}$ in NH summer, over land. As shown in Figure 3, about 70% of all lightning occurs between 30°S and 30°N , echoing the distribution of convective activity. In the tropics there is no seasonal cycle in the lightning frequency. The seasonal cycle in midlatitude lightning flash rate (with more lightning in the summer months) is due mostly to differences in the number of storms (i.e., presumably, in CAPE), rather than in differences in the flash rate per storm.

F is maximum at 1500–1800 local time, with much smaller amplitude variation over the oceans than over land. The diurnal cycle at any fixed location is due in part to a cycle in flash rate per storm and in part to the diurnal cycle in the number of storms.

Lightning production requires both high vertical velocity and high upward water flux in the charging or mixed phase zone. Water fluxes in this region are relatively weak in many oceanic storms, which may provide a clue to the large land–ocean differences in F indicated in Figure 3: $F_{\text{storm}}(\text{on land}) \approx 2 \times F_{\text{storm}}(\text{over ocean})$, but $F_{\text{total}}(\text{land}) \approx 10 \times F_{\text{total}}(\text{ocean})$. (Probably the difference is enhanced by large continental storms.)

The electric field distribution in and below a thunderstorm determines whether the lightning produced is IC or C–G. Globally, the ratio IC/C–G ranges from about 1 to 5, increasing with increasing latitude. This latitudinal variation probably occurs because the base of the charging zone is higher and the depth of the charging zone larger in the tropics than in midlatitudes.

Summary

Lightning is an electrical discharge that arises in the high electric fields inside a thunderstorm. While neither the field generation mechanisms nor the details of the lightning initiation are well understood, we have enough information to begin to relate lightning to the atmospheric conditions in which it originates. Lightning frequency, polarity, intensity, and the spatial distribution of lightning flashes in principle carry information about spatial distributions of updraft velocities and hydrometeors, particularly in the mixed-phase regions of storms. Lightning can be sensed at great distance and it yields a measure of the state of a storm that is independent of those measures derived from meteorological instruments. Thus, as our understanding of the links of lightning to other atmospheric phenomena improves, we can design ways to utilize lightning data to improve storm prediction. Moreover, distributions of lightning can provide long-term information on the atmospheric portion of the hydrological cycle. Incorporation of lightning-related variables into the suite of measures used routinely to diagnose surface temperature and atmospheric stability may eventually aid in monitoring global and regional climate change.

Introduction

Science often advances at a deliberate and cautious pace. Over a hundred years passed before the persistent reports of luminous events in the stratosphere and mesosphere associated with tropospheric lightning were accepted by the scientific community. Since 1886, dozens of eyewitness accounts, mostly published in obscure meteorological publications, have been found alongside articles describing meteorological esoterica such as half-meter-wide snowflakes and toads falling during rain showers. The phenomena were variously described using terms such as ‘cloud-to-space lightning’ and ‘rocket lightning’. A typical description might read ‘In its most typical form it consists of flames appearing to shoot up from the top of the cloud or, if the cloud is out of sight, the flames seem to rise from the horizon’. Such reports were largely ignored by the nascent atmospheric electricity community, even when they were posted by a Nobel Prize-winning physicist. As early as 1925, C.T.R. Wilson proposed possible mechanisms to explain such phenomena. In 1956 Wilson commented

It is quite possible that a discharge between the top of the cloud and the ionosphere is a normal accompaniment of a lightning discharge to earth ... a diffuse discharge between the top of the cloud and the upper atmosphere ... many years ago I observed what appeared to be discharges of this kind from a thundercloud below the horizon. They were diffuse, fan-shaped flashes, green in color ... extending up into a clear sky.

During the last three decades, several compendia of similar subjective reports from credible witnesses worldwide were prepared by Otha H. Vaughan (NASA Marshall) and the late Bernard Vonnegut (The State University of New York – Albany). The events were widely dispersed geographically from equatorial regions to above 50° latitude. About 75% of the observations were made over land. The eyewitness descriptions shared one common characteristic: they were perceived as highly atypical of ‘normal’ lightning. The reaction of the atmospheric science community could be summarized as indifference at best. Then, as so often happens in science, serendipity intervened.

Hard Evidence Emerges

The air of mystery began to dissipate at 0414 UTC on 6 July 1989. Scientists from the University of Minnesota, led by Professor John R. Winckler, were testing a low-light CCD video camera system (LLTV) for a forthcoming rocket flight at an observatory in central Minnesota. The resulting tape contained, quite by accident, two fields of video that provided the first hard evidence for what are now called sprites. The twin pillars of light were assumed to originate with a thunderstorm system some 250 km

to north along the Canadian border. The storm system, while not especially severe, did contain a larger than average number of positive-polarity cloud-to-ground (+CG) lightning flashes. From this singular observation emanated a decade of fruitful research into the electrodynamics of the middle atmosphere.

In the early 1990s, NASA scientists searched tapes from the Space Shuttle’s LLTV camera archives and confirmed at least 17 apparent sprites above storm clouds occurring worldwide. The orbital perspective suggested a relationship between sprites and tropospheric lightning. The specific lightning flashes associated with the observed sprites were often among the brightest in the region. The sprites occurred within milliseconds of the brightest cloud illumination, and were apparently triggered by especially energetic discharges within the storm cell. The parent convective systems, while often larger than their neighbors, had otherwise unexceptional flash rates. [Figure 1](#) portrays the global distribution of sprite reports. By late 1999 and early 2000 the first sprites (and elves) had been detected above European convective storms.

By 1993, NASA’s Shuttle Safety Office had developed concerns that this newly discovered ‘cloud-to-space lightning’ might be fairly common and thus pose a potential threat to Space Shuttle missions, especially during launch or recovery. Based upon the available evidence, the author’s hunt for these elusive events was directed above the stratiform regions of large mesoscale convective systems (MCSs), known to generate relatively few but often very energetic lightning discharges. On the night of 7 July 1993, an LLTV was deployed for the first time at the Yucca Ridge Field Station (YRFS), on high terrain about 20 km east of Fort Collins, Colorado, USA. Exploiting an uninterrupted view of the skies above the High Plains to the east, the LLTV was trained above a large nocturnal MCS in Kansas, some 400 km distant. Once again, good fortune intervened as 248 sprites were imaged over the next four hours. Analyses revealed that almost all the sprites were associated with +CG flashes, and assumed an amazing variety of shapes ([Figure 2](#)). Within 24 h, in a totally independent research effort, sprites were imaged by a University of Alaska team on board the NASA DC8 aircraft over Iowa. The following summer, the University of Alaska’s flights provided the first color videos detailing the red sprite body with bluish, downward-extending tendrils. The same series of flights documented the truly bizarre blue jets.

By 1994 it had become apparent that there was a rapidly developing problem with the nomenclature being used to describe the various findings in the scientific literature. The name ‘sprite’ was elected so as to avoid employing a term that might presume more about the physics of the phenomena than our knowledge warranted. Sprite replaced terms as ‘cloud-to-space’ lightning and ‘cloud-to-ionosphere discharge’ and similar appellations that were initially in use. The intentionally fanciful names given to phenomena were selected in the same spirit. Today a host of phenomena have been named: sprites, blue jets, blue starters, elves, sprite halos, and trolls, with

Figure 1 Global distribution of reports of sprites and elves (as of 2000). The US events are shown schematically as hundreds of storms have been monitored in that region.

perhaps others remaining to be discovered. Collectively they have been termed Transient Luminous Events (TLEs).

A Description of TLEs

Since the first sprite observations in 1989, the scientific community's misperception of the middle atmosphere above thunderstorms as 'uninteresting' has completely changed. Much has been learned about the morphology of TLEs in recent years. Sprites can extend vertically between 95 km and less than 30 km. While telescopic investigations reveal that individual tendril elements may be of the order of 10 m across, the total illuminated volume can exceed 10^4 km^3 . Sprites are almost always preceded by +CG flashes, with time lags of less than

1 ms to over 100 ms. To date, there are only two documented cases of sprites associated with negative-polarity CGs. The sprite parent +CG peak currents range widely, from under 10 kA to over 100 kA, though on average the sprite +CG peak current is 50% higher than other +CGs in the same storm. High-speed video images (1000 fps) suggest that many sprites usually initiate around 70–75 km from a small point, and first extend downward and then upward development at speeds of around 10^7 m s^{-1} . Sprite luminosity on typical LLTV videos can endure for tens of milliseconds. Photometry suggests, however, that the brightest elements usually persist for a few milliseconds, though occasionally small, bright 'hot spots' linger for tens of milliseconds. By 1995, sprite spectral measurements by Russell Armstrong of Mission Research Corporation confirmed the presence of the N_2 first positive emission lines. In 1996, photometry provided clear evidence of ionization in some sprites associated with blue emissions within the tendrils and sometimes the sprite body. Peak brightness within sprites is on the order of 1000 kR. In seven years of observations at Yucca Ridge, sprites were typically associated with larger storms ($>10^4 \text{ km}^2$ radar echo), especially those exhibiting substantial regions of stratiform precipitation. The TLE-generating phase of High Plains storms averages about 3 h. The probability of optical detection of TLEs from the ground in Colorado is highest between 0400 and 0700 UTC. It is suspected that sprite activity is maximum around local midnight for many storms around the world. The TLE counts observed from single storm systems has ranged from 1 to 776, with 48 as an average count. Sustained rates as high as once every 12 s have been noted, but more typical intervals are on the order of 2–5 min.

Like snowflakes, no two sprites are alike. Developing a taxonomy to describe sprite shapes has proven to be a challenge, though several names have come into common use. The vertically oriented, narrow (order 1 km) columnar sprites are often referred to as c-sprites (Figure 3). Sprites that have

Figure 2 A low-light television image of a sprite at a range of about 600 km from the camera. The sprite extends from about 90 km downward to about 40 km (The bright spot at the lower left is Jupiter).

Figure 3 An example of thin columnar sprites (c-sprites) with downward-extending tendrils. (The bright spot is Jupiter.)

pronounced downward-extending tendrils and upward-flaring streamers have been referred to as ‘carrots’ (Figure 4). Some amorphous and apparently structureless events have been termed ‘smudges’. Rapid-fire successions of sprites appearing to propagate above a cloud top have been termed ‘dancers’ (Figure 5).

Can sprites be detected with the naked eye? The answer is a qualified yes. Most sprites do not exceed the threshold of detection of the dark-adapted human eye, but some do. Naked-eye observations require a dark (usually rural) location, no moon, very clean air (such as visibilities typical of the western United States), and a dark-adapted eye (5 min or more). A storm located 100–300 km distant is ideal if it contains a large stratiform precipitation area with +CGs. The observer should stare at the region located some 3–5 times the height of the storm cloud (Figure 6). It is best to shield the eye from the lightning flashing within the parent storm. Often sprites are best seen out of the corner of the eye. The event is so transient often observers cannot be sure of what they may have seen. The perceived color may not always appear ‘salmon red’ to

Figure 4 A close-range (around 175 km) view of a ‘carrot’ type sprite with both downward-extending thin tendrils and bright upward branches.

any given individual. Given the human eye’s limitations in discerning color at very low light levels, some report seeing sprites in their natural color but others see them as white or even green (as did C.T.R. Wilson). Figure 7 is an LLTV sprite imaged rendered to what are believed to be close to the sprite’s true colors.

While most TLE discoveries came as a surprise, one was predicted in advance from theoretical arguments. In the early 1990s, Stanford University researchers proposed that the electromagnetic pulse (EMP) from CG flashes could induce a transient glow at the lower ledge of the ionosphere between 80 and 100 km altitude (Figure 8). Evidence for this was first noted in 1994 using LLTV at Yucca Ridge. Elves were confirmed the following year by photometric arrays deployed at Yucca Ridge by Tohoku University. Elves, as they are now called, are believed to be expanding quasi-toroidal structures that attain a width of up to several hundred kilometers. (The singular is elve, rather than elf, in order to avoid confusion with ELF (extremely low frequency) radio waves which are used intensively in TLE studies.) Photometric measurements suggest that an elve’s intrinsic color is red owing to strong N_2 first positive emissions. While relatively bright (1000 kR), their duration is $<500 \mu s$. Elves follow very high peak current (often >100 kA) CGs, most of which are positive in polarity, by about $\sim 300 \mu s$. Stanford University researchers, using sensitive photometric arrays, documented the outward and downward expansion of the elve’s disk. They also suggest many more dim elves occur than are detected with conventional LLTVs. These fainter elves have been suggested to be more evenly distributed between positive- and negative-polarity CGs.

It has been determined recently that some sprites are preceded by a diffuse disk-shaped glow that lasts about a millisecond and superficially resembles an elve. However, these structures, now called ‘sprite halos’, are less than 100 km wide, and propagate downward from about 85 to 70 km altitude. Sprite elements sometimes emerge from the lower portion of the sprite halo’s concave disk.

Blue jets are rarely observed from ground-based observatories, in part because of atmospheric scattering of the shorter wavelengths. LLTV video from aircraft missions revealed blue jets emerging from the tops of electrically active thunderstorms. The jets propagate upward at speeds of $\sim 100 \text{ km s}^{-1}$, reaching terminal altitudes around 40 km. Their estimated brightness is on the order of 1000 kR. Blue jets do not appear associated with specific CG flashes. Curiously, however, CG lightning activity appears to cease for several seconds within a 15 km radius after each occurrence of a blue jet. Some blue jets appear not to extend very far above the clouds, only propagating as bright channels for a few kilometers above the storm tops. These nascent blue jets have been termed blue starters. During the 2000 observational campaign at Yucca Ridge, the first blue starters ever imaged from the ground were noted. They were accompanied by very bright, short-lived (~ 20 ms) ‘dots’ of light at the top of MCS anvil clouds. There have been anecdotal associations of blue jets with hail-producing storms. A NASA ER2 pilot flying over the Dominican Republic above Hurricane Georges in 1998 described seeing luminous structures that resembled blue jets.

The troll is the most recent addition to the TLE family. In LLTV videos, trolls superficially resemble blue jets, yet they are

Figure 5 Example of a 'dancing' sprite in which five separate sprites appear in succession moving north-eastward above the trailing stratiform region of a mesoscale convective system in eastern Nebraska. Three +CGs were detected by the NLDN that were associated with given sprites. It is believed the three +CGs are part of a continuous discharge characterized by a >100 km long horizontally propagating 'spider' lightning discharge. The sprite images were obtained with an off-the-shelf ITT Night Vision systems mated with a DV camcorder.

clearly dominated by red emissions. Moreover, they occur after an especially bright sprite in which tendrils have extended downward to near cloud tops. The trolls exhibit a luminous head leading a faint trail moving upward initially around 150 km s^{-1} , then gradually decelerating and disappearing by 50 km. It is still not known whether the preceding sprite tendrils actually extend to the physical cloud tops or whether the trolls emerge from the storm cloud per se.

The Lightning Source Term for TLEs

Worldwide, a variety of storm types have been associated with TLEs. These include the larger mid-latitude MCS, tornadic squall lines, tropical deep convection, tropical cyclones, and winter snow squalls over the Sea of Japan. It appears, however, that the central United States may be home to some of the most prolific TLE producers, even though only a minority of High Plains thunderstorms produce TLEs. Some convective regimes, such as supercells, have yet to be observed producing many TLEs, and the few that have been observed are mostly confined to the stratiform precipitation region that may develop during

the late mature and decaying stages. Furthermore, the vast majority of +CGs, even many with peak currents above 50 kA, produce neither sprites nor elves that are detectable using standard LLTV systems. While large peak current +CGs populate both MCSs and supercells, only certain +CGs possess characteristics that generate sprites or elves.

Monitoring of ELF radio emissions in the Schumann resonance bands (8–120 Hz) has provided a clue to what differentiates the TLE parent CG from 'normal' flashes. The background Schumann resonance signal is produced from the multitude of lightning flashes occurring worldwide. It is generally a slowly varying signal, but periodically brief amplitude spikes, called Q-bursts, are noted. Their origin was a matter of conjecture for several decades. In 1994, visual sprite observations at Yucca Ridge were coordinated in real time with ELF transients (Q-bursts) detected at a Rhode Island receiver station operated by Earle Williams of the Massachusetts Institute of Technology. This experiment, repeated many times since, clearly demonstrated that Q-bursts are companions to the +CG flashes generating both sprites and elves. ELF measurements have shown that sprite parent +CGs are associated with exceptionally large charge moments (300 to >2000 C km).

Figure 6 The geometry of sprite watching.

The sprite +CG ELF waveform spectral color is 'red', that is, peaked toward the fundamental Schumann resonance mode at 8 Hz. Lightning charge transfers of hundreds of coulombs may be required for consistency with theories for sprite optical intensity and to account for the ELF Q-burst intensity. Lightning that causes elves has a much flatter ('white') ELF spectrum and, though associated with the very highest peak current +CGs, exhibits much smaller charge moments (<300 C km).

Recent studies of High Plains MCSs confirm that their electrical and lightning characteristics are radically different from the textbook 'dipole' thunderstorm model, derived largely from studies of rather small convective storms. Several horizontal laminae of positive charge are found, one often near the

0°C layer, and these structures persist for several hours over spatial scales of ~ 100 km. With positive charge densities of $1\text{--}3$ nC m $^{-3}$, even relatively shallow layers (of order 500 m) covering 10^4 to 10^5 km 2 can contain thousands of coulombs. Some 75 years ago, C.T.R. Wilson postulated that large charge transfers and particularly large charge moments from CG lightning appear to be a necessary condition for conventional breakdown that could produce middle-atmospheric optical emissions. Sprites occur most readily above MCS stratiform precipitation regions with radar echoes larger than $\sim 10^4$ km 2 . It is not uncommon to observe rapid-fire sequences of sprites

Figure 7 A low-light television image of a sprite at a range of about 400 km from the camera. The glow on the horizon is from the parent lightning stroke. The sprite has been colorized to show what is believed to be close to the true color.

Figure 8 Low-light television image of a large elve above a distant thunderstorm. Note the lower intensity near the center, indicative of the expanding toroidal-shaped structure of the elve.

Table 1 Current ideas on TLE storm/lightning parameters in selected storm types

	<i>Core of supercells</i>	<i>MCS stratiform region</i>	<i>'Ordinary' convection</i>
+CG peak currents	> ~40 kA	> ~60 kA	~30 kA
Storm dimension	10–20 km	10–500 km	<100 km
Spider discharges	Few/small	Many/large	Some
Continuing current	Short if any	Longest	Some
+CG Channel height	10–15 km?	5 km?	10 km?
Sprites occur?	No (except at end) ^a	Many	Rare?
Elves occur?	No (except at end) ^a	Many	Rare?
Blue jets occur?	Yes?	Rare?	Rare?

^aSome supercells may generate a few sprites during their final phase when/if extensive stratiform develops.

propagating above storm tops, apparently in synchrony with a large underlying horizontal lightning discharge. One such 'dancer' included a succession of eight individual sprites within 700 ms along a 200 km long corridor. This suggests a propagation speed of the underlying 'forcing function' of $\sim 3 \times 10^5$ m s⁻¹. This is consistent with the propagation speed of 'spider' lightning – vast horizontal dendritic channels tapping extensive charge pools once a +CG channel with a long continuing current becomes established.

It is suspected that only the larger MCS, which contain large stratiform precipitation regions, give rise to the +CGs associated with the spider lightning networks able to lower the necessary charge to ground. The majority of sprite parent +CGs are concentrated in the trailing MCS stratiform regions. The radar reflectivities associated with the parent +CGs are relatively modest, 30–40 dBZ or less. Only a small subregion of trailing stratiform area produces sprite and elves. It would appear that this portion of the MCS possesses, for several hours, the requisite dynamical and microphysical processes favorable for the unique electrical discharges that drive TLEs. [Table 1](#) and [Table 2](#) summarizes the relationships between lightning and the major TLE types.

The Causes of Transient Luminous Events

TLEs have captured the interest of many theoreticians. Several basic mechanisms have been postulated to explain the observed luminous structures. These include sprite excitation by a quasi-electrostatic (QE) mechanism. Sprite production by runaway electrons in the strong electric field above storms has been suggested. The formation of elves from lightning electromagnetic pulses is now generally accepted. More than one mechanism may be operating, but on different temporal and spatial scales, which in turn produce the bewildering variety of TLE shapes and sizes. Absent from almost all theoretical modeling efforts are specific data on key parameters characterizing lightning flashes that actually produce TLEs. Many modelers refer to standard reference texts, which, in turn, tend to compile data taken in storm types and locations that are not representative of the nocturnal High Plains. Specifically, many invoke the conventional view that the positive charge reservoir for the lightning is found in the upper portion of the cloud at

Table 2 Current speculations about characteristics of TLEs and their parent lightning (none for blue jets)

	<i>Sprite</i>	<i>Elve</i>	<i>Blue jet</i>
<i>Color of emission</i>	Red top/blue base	Red?	Deep blue
Polarity of parent CG	Positive	Positive (mostly)	None
+CG Peak current	> ~50 kA	> ~100 kA	None
Charge transferred	Largest	Large	N/A
Charge moment	Largest	Large	N/A
Parent CG location	Stratiform area	Stratiform area?	N/A
Parent CG vertical channel height	5 km?	10 km?	N/A
D I/DT value	?	Large?	N/A
Total flash duration	Very long	Short?	N/A
Spider involved	Yes?	No?	N/A
Continuing current duration	Very long?	Short if any?	N/A
VLF/ELF slow tail	Distinct	Possible	N/A
ELF spectral color	Red	White	None
VLF audio character	Low frequency	Higher frequency	None
Duration of TLE	1–150 ms	0.5 ms	100–200 ms
Altitude range of TLE	25–95 km	75–105 km	Cloud–40 km
Onset delay after CG	1–100 ms	0.325 ms	N/A
Brightness	50–1000 kR	1000 kR	1000 kR
Horizontal size of emission	100 m–100 km	100–400 km	~2 km

altitudes of ~10 km. The positive dipole (or tripole) storm model has been found wanting in many midcontinental storms. A survey was made of the range of lightning parameters used in over a dozen theoretical modeling studies. While the proposed heights of the vertical +CG channel ranges from 4 to 20 km, there is a clear preference for 10 km and above. The amount of charge lowered varies over three orders of magnitude, as does the time scale over which the charge transfer occurs. Only a few papers consider the possible role of horizontal components of the parent discharge. The charge moment (in C km) – not the peak current as measured by the National Lightning Detection Network (NLDN) – is the key parameter in the basic QE conventional breakdown mechanism first proposed by Wilson. The key physics of the problem appears to involve the altitude and magnitude of the removed charge and the time scale on which this occurs, parameters about which little agreement exists. Many theorists note that even with an assumed tall +CG channel (~10 km), extremely large (~100 C) charge transfers, typically ten times larger than in 'conventional' lightning, are required to trigger sprites. Some models yield a thousandfold enhancement in optical intensity at 75 km for a doubling of lightning charge removal altitude from 5 to 10 km. The use of shorter channels to ground, say 5 km, would imply truly large charge transfers. Evidence is accumulating that indeed such may be the case. Recent estimates of charge moments associated with sprite parent lightning +CGs suggest values are typically at least 300–600 C km, and often much larger.

While the various models simulate optical emissions bearing some (though in many cases rather minimal) resemblance to the observations, the wide ranges in the lightning

source term parameters used by modelers do not appear physically realistic. If, in fact, such a range of lightning characteristics could produce sprites, why does only a very small subset of +CGs (<1:20 even in active storms) actually produce observable TLEs (with current sensors)? It appears that most models have made assumptions about the lightning in order to produce something resembling a TLE, rather than starting with hard physical constraints on the source term. The reason, of course, is that there is very little data on the actual CGs that generate specific TLE occurrences.

Shortly after the confirmation in 1993 of sprites as a frequently occurring phenomenon, speculation began that meteors might serve as a trigger for sprites in the intense electric fields above large MCS. This notion was quickly dismissed during several summers of observations of meteor showers coincident with large MCS systems over the United States, which found no sprite–meteor pairings. However, in 1998, a small meteor descending below 100 km altitude appeared to have triggered a sprite above an MCS. No coincident CG lightning flash was observed and the sprite appeared to originate close to the end of the luminous meteor trail. Even more curiously, a jetlike feature appeared to move about 10 km back up the ionized trail left by the meteor. This (so far) unique event illustrates how complex and interrelated middle-atmospheric electrical discharge phenomena may be.

Experimental Measurements

Since the late 1990s more and more complex measurement programs have begun to be undertaken to study TLEs. One of the more important gaps in our knowledge concerns the electric environment above large thunderstorms during TLE episodes. Consequently, the 1999 NASA Sprite Balloon Campaign, directed by E.A. Bering of the University of Houston, conducted several high-altitude balloon flights. The last mission flew out of Ottumwa, Iowa, on the night of 20–21 August 1999. The balloon payload floated at 32 km and drifted westward at ~30 knots. Ground-based LLTV observations were made from three sites (in Wyoming, South Dakota, and Colorado). All three stations had clear skies. There were two small TLE-producing storms, one in eastern South Dakota and one in central Kansas. Of 67 TLEs seen by at least one station or the balloon, 5 were seen by two or more stations. The balloon data at a typical range of 300 km show that the sprite is accompanied by a positive vertical electric field pulse of $\sim 0.2 \text{ V m}^{-1}$. Curiously, no perturbation in any component of the electromagnetic fields was observed during the several milliseconds between the lightning flash and a sprite. Also, two very bright elves were detected by ground and balloon optical sensors. The NLDN, however, failed to compute any associated CG. Analysis of the raw network sensor data did reveal that the elve parent lightning events were each observed by over 75% of the NLDN's sensors nationwide. This powerful sferic was so complex as to prevent classification by the NLDN algorithms. Preliminary results from this flight have indicated that more data are required before we can understand the complex physics involved.

Until the summer of 2000, no lightning flash known to produce a sprite or elve had ever been well characterized. To

simulate complex TLEs, modelers require information on the total charge removed and its waveform, the continuing current characteristics, the rate and altitude from which charge was removed, and the geometry of the vertical and, especially, horizontal lightning channels. Between 22 May and 16 July 2000, a major field observation effort called the Severe Thunderstorm Electrification and Precipitation Study (STEPS) was undertaken. The STEPS domain, located 100–400 km east-south-east of Yucca Ridge, was ideally situated for acquiring a wide array of optical measurements of TLEs above the storm concurrently with the lightning discharges below. With the inclusion of the 3D lightning mapping array (LMA) from New Mexico Tech, analyses of STEPS data will facilitate determination of the unique lightning discharges that give rise to TLEs. STEPS may confirm whether massive 'spider' discharges are a necessary condition for sprites.

Scheduled programs during the early 2000s include a joint US–Israeli sprite-observing mission on the Space Shuttle. Plans are also under way for Taiwan to launch a sprite-monitoring satellite.

Why Study TLEs?

Apart from their intrinsic scientific interest, there may be some rather practical reasons to explore TLEs in more depth. It has been suggested that there may be significant production of nitrogen oxides (NO_x) in the middle atmosphere by sprites. This becomes even more interesting in the light of recent observations that regional smoke palls from biomass burning radically enhance the percentage of +CGs within storms, and thus increase sprite counts (and middle atmosphere NO_x production?). Currently, no global chemical model accounts for any potential effects of TLEs.

Once a better estimate of NO_x production per sprite is obtained, it will be necessary to know the global frequency and distribution of sprites. It has been demonstrated that several Schumann resonance monitoring sites working in tandem are capable of obtaining a worldwide TLE census.

There is growing interest in determining the sources of unusual infrasound emissions detected above sprite-capable MCSs as determined by NOAA's Environmental Technology Laboratory near Boulder, Colorado. TLEs thus produce optical, radiofrequency, and acoustic emissions that have the potential of mimicking or masking signatures from clandestine nuclear tests. Such findings may have important implications for global monitoring efforts supporting the Comprehensive Test Ban Treaty.

TLEs may contribute in ways not yet understood to the maintenance of the global electrical circuit. To quantify the impacts of TLEs, we require information on the global frequency (now roughly estimated between 1 and 10 per minute) and their geographic distribution. Recent findings may clarify some of the broader issues concerning any potential TLE hazards to aerospace safety above 15 km.

Introduction

Forensic meteorology is the study of past weather events for the primary purpose of assisting a court of law in adjudicating disputes in which weather may have been a factor. The task of a forensic meteorologist is to diligently investigate the weather conditions pertinent to the litigation and objectively present to the court the most accurate description possible of the relevant meteorological events. Expert testimony by a meteorologist often provides crucial information in various types of civil and criminal proceedings.

Civil litigation is often initiated when a personal injury or financial loss occurs, or when a contractual dispute cannot be resolved. In many cases the weather is a contributing factor, or even the primary cause of the loss or dispute. For example, weather frequently contributes to maritime cargo losses, aircraft and highway accidents, property damage, construction delays, air pollution emergencies, slip and fall injuries, and structural failures. The party sustaining the loss or injury may seek compensation through the legal system from another party who is alleged to be responsible for the incident. A judge, jury, or other adjudicative body must determine the facts of the case and make a decision in favor of one of the parties in the litigation, either the plaintiff or the defendant. If the weather was a factor in the incident or dispute on which the lawsuit is based, then expert testimony about the weather conditions relevant to the case must be presented to the adjudicative body in a courtroom or other judicial setting. Meteorological analysis and testimony are sometimes necessary simply to rule out weather as a contributing factor. Together with other facts, testimony, opinions, exhibits, and evidence, the adjudicative body considers the relevant weather evidence and opinions in making its determination.

In addition to civil litigation, testimony about the weather is occasionally required in criminal proceedings. For example, the ability of an eyewitness to identify an alleged assailant in low natural lighting is occasionally an issue in criminal trials. In such cases a meteorologist may be called to testify about the sky conditions, phase of the moon, or sunrise and sunset times. Other criminal proceedings have depended on meteorological analysis and testimony as it relates to the decomposition of the bodies of murder victims, the transport of odors from illegal drugs, the death of children trapped inside motor vehicles exposed to intense sunlight, and various types of criminal negligence.

In a broader sense, the work of a forensic meteorologist is not necessarily limited to civil litigation and criminal prosecutions. For example, a windstorm that causes property damage may result in a claims dispute between an insured party and its insurer. A meteorologist may be hired by one of the parties in the dispute to ascertain the peak wind speed during the storm. The conclusions of the meteorologist may be sufficient to allow the client to make a determination about the

claim and settle the dispute with the opposing party, thus avoiding the effort and expense of a lawsuit. Similarly, a forensic meteorologist may be hired to provide information and expert opinion about past weather events to parties involved in administrative or regulatory disputes with government agencies.

The Practice of Forensic Meteorology

General Procedures and Considerations

Technical experts are often retained by attorneys representing the parties involved in a lawsuit. The immediate purpose of retaining a meteorologist is to obtain information and expert opinion about the weather conditions so that the attorney can evaluate, with assistance from the expert, the importance of weather to the case. The attorney will consider how the weather facts and opinions may support or refute theories for the causation of the loss that led to the litigation. If the meteorological information and opinions are relevant and helpful, the weather expert may be asked by the attorney to prepare a formal report, evaluate the reports and opinions of the meteorologist (if any) working for the opposing legal counsel, assist the attorney in evaluating the merits and demerits of the case from a technical perspective, develop exhibits for presentation at trial, and provide expert testimony and opinions at deposition and trial.

The expert investigating and testifying about the weather should be a meteorologist with sufficient knowledge, skill, experience, and education to offer an opinion about the particular weather conditions related to the litigation. Although meteorologists are not usually granted professional licenses like engineers or architects, the American Meteorological Society, for example, has a certification program for consultants, identified as Certified Consulting Meteorologists, that involves extensive testing and board review. Many attorneys find that the certification assists them in identifying qualified experts. The forensic meteorologist must also have a high degree of integrity and composure under pressure, so that the expert testimony that he or she gives in the courtroom is trustworthy, unbiased and professional.

The admissibility of expert opinions in the federal courts of the United States is governed by the 'Daubert test' in which the judge assesses whether the reasoning or methodology underlying the opinion is scientifically valid and the offered testimony is relevant to the case. Many non-federal courts still adhere to the earlier 'Frye test' in which expert opinions must be based on principles and techniques that are 'generally accepted' as reliable within the relevant scientific community.

Before accepting work as an expert, the forensic meteorologist should inquire about the nature of the case and the parties and attorneys involved, in order to avoid possible conflicts of interest. A conflict may arise if the expert has had prior exposure

to the facts and legal arguments of the case or if the opposing attorney is a regular client of the expert, particularly for cases of a similar nature. In some instances the expert should decline to accept the work if the case involves a special area of meteorology in which the expert has limited knowledge or training. For example, an expert in air pollution meteorology may refer the client to an aviation weather expert if the case involves an aircraft accident in a severe thunderstorm.

After accepting the case, the weather expert should obtain all the information that the attorney possesses that might be relevant to the meteorological investigation. This information will include, at a minimum, the date, time, location, and nature of the event that led to the litigation. It may also include reports and statements describing the event that were prepared by investigative agencies, law enforcement officers, or eyewitnesses. For example, the National Transportation Safety Board of the United States produces investigative reports that provide information about the particulars and contributing factors in aircraft accidents. The testimony of eyewitnesses regarding the weather conditions can sometimes provide descriptive details about a weather event that would not be evident in official meteorological data. The expert may also find it useful to visit the site of the incident to assess the importance of exposure, surrounding terrain, and site orientation to the analysis and interpretation of the meteorological events.

The Value of Meteorological Data and Analysis

Although the attorney retaining the expert may have a substantial amount of information about the event, a forensic meteorologist cannot offer a reliable opinion until weather data are obtained and reviewed. The nature and quality of the data needed to formulate expert opinions depends on the nature of the case and the relative importance of weather to the arguments and theories in the litigation. In the case of a slip and fall injury, it may only be necessary to obtain hourly rainfall data from a nearby weather station. In the case of a fatal aircraft accident, a wide variety of data may be needed to formulate a clear and complete description of the weather conditions at the time and location of the accident. The data may include surface weather observations, upper-air weather charts, satellite and radar images, lightning strike data, aviation weather forecasts, and pilot reports of weather conditions aloft.

Forensic meteorological investigations often depend on the analysis of severe weather phenomena that have significant variations over small temporal and spatial scales. For example, a severe thunderstorm can create strong winds and large hail that cause isolated property damage in a few seconds to minutes. The ability to reconstruct past weather for forensic purposes has been greatly enhanced by recent advances in observational techniques that target mesoscale weather phenomena. For example, the National Weather Service of the United States operates a network of Doppler weather radar stations that provide nearly complete and continuous coverage of the country. Similar radar networks are found in other countries. The radar monitoring of severe weather and the archiving of the radar data have allowed forensic meteorologists to develop more accurate and detailed descriptions of severe weather events.

Similarly, the weather is monitored continually from space by geostationary and polar-orbiting satellites. Improvements in the resolution of the on-board sensors and the addition of more observing channels at infrared wavelengths allows forensic meteorologists to investigate past weather events in greater detail. For example, combinations of data from different infrared channels permits the identification of potential aviation hazards such as fog or airframe icing. Other satellites are capable of measuring ocean wave heights and estimating surface wind speeds at sea, which is valuable information for the investigation of cargo and ship losses during intense storms.

Other advances in meteorology are related to improvements in computer models of the atmosphere. The ability to computationally simulate or analyze mesoscale weather phenomena has greatly improved. The global re-analysis of historical weather data with computer models that are also used in operational weather forecasts has provided another new tool for the forensic investigator.

Acquisition of Weather Data

The meteorological data used in forensic work are commonly stored in government archives and can be accessed by the general public for usually modest fees. The primary sources of data in the United States are the National Climatic Data Center, which is part of the National Oceanic and Atmospheric Administration, and Regional Climate Centers and State Climatologists. Similar government archives are operated by the weather services of other countries. In addition to national government sources, a number of local government agencies, universities, and private companies archive meteorological data and operate weather observing stations in special monitoring networks. While anyone involved in litigation can obtain weather data, a forensic meteorologist is usually more efficient in selecting and obtaining the relevant data and organizing it into a coherent source of information for the analysis of weather events.

The collection, archiving, and retrieval of meteorological data had undergone considerable change in recent years, affecting the practice of forensic meteorology. In the past most meteorological data were recorded and archived on paper or film. For example, wind data were recorded on instrument recorder charts, radar scope images on film, and surface observations on handwritten forms. The data and analysis techniques were often limited in quantity and complexity. Forensic meteorologists usually ordered, and in many cases continue to order, paper copies of data and images that bear a fixed certification and seal of authenticity from the government agency providing the data. The physical seal and certification of the data copy are still regularly used as a means of authenticating the copy for admission into evidence at trial. Production and delivery of the hard-copy data and images by the data supplier often resulted in waiting times of a few weeks to months. Analysis of the data by a forensic meteorologist was labor-intensive, particularly for cases in which years of data had to be reviewed to determine normal climatological conditions, since the data had to be extracted from the certified paper forms.

The recording, storage, and delivery of data on paper, microfiche, and film is rapidly diminishing. Low-cost computer storage of data, data-intensive observational systems such as

Doppler weather radar and multichannel satellite sensors, complex computer models of the atmosphere and ocean, digital surface weather sensors, computer networks, and the Internet are radically changing the work of the forensic meteorologist. Many government and private data sets are now maintained on computer servers on the Internet and are easily accessible at low or no cost to the end user. Even large data sets, such as satellite and radar data, can be extracted from computer tapes at government archives and delivered to the end-user by file transfers over the Internet. Many data providers are also providing large data sets on CD-ROM and DVD. Large quantities of data can thus be retrieved and analyzed on the computer workstations of forensic meteorologists. Waiting periods for data delivery have generally been reduced from weeks and months to minutes and days. While the time required to acquire and analyze the data on a per-unit basis has been substantially reduced, the quantity and variety of data available for forensic work has increased dramatically, so that the total amount of effort in a typical investigation has not diminished. Even so, improved access to data often allows experts to provide their clients with preliminary analysis and opinions in a time frame shorter than previously possible.

The physical certification of digitized data is often impractical, if not impossible. The authenticity of digitized meteorological data as admissible trial evidence is usually not problematic, provided the testifying expert can demonstrate that the data was obtained from reliable sources and is customarily used by meteorologists in their work.

Reports and Testimony

After the weather data has been obtained and analyzed, a report is made to the client either verbally or in writing. A formal report that includes expert opinions is sometimes required by the client or by the judicial rules governing the litigation. The report becomes a basic reference document for future testimony by the expert.

Before a case goes to trial, a discovery period occurs when the attorneys in the litigation request copies of the documents and information used or prepared by the other side's technical experts. The information includes the data gathered and any written reports prepared by the weather expert. Furthermore, the expert is questioned in a deposition by the opposing legal counsel to discover the expert's opinions and the foundational basis for those opinions. The discovery and evaluation of the weather data and expert opinions sometimes encourage a settlement between the opposing parties, particularly if the weather was the primary cause of the loss or dispute that initiated the lawsuit.

As the trial approaches, the expert prepares exhibits that display the data and information relevant to the issues of the case. The exhibits are often directly derived from diagrams, tables, and images found in the expert's report. The availability of digitized data has led to improvements in the presentation of meteorological information in the courtroom. Radar and satellite digital images and computer simulations of weather events can easily be annotated for trial presentation and stored on a CD-ROM. Using a high-resolution projector attached to a laptop computer, the testifying expert can display the images in the courtroom using animation sequences, stop-action

frames, zoom views, and various enhancements. Presentations of this kind allow the jury or judge to arrive at a better understanding of the weather conditions associated with the event that led to the litigation. In fact, many lay people who serve on juries see animated satellite and radar images on the weather segments of television news shows and are somewhat familiar with basic meteorological concepts related to these observations, prior to seeing such data in the courtroom.

The expert should assist the attorney in preparing for the expert's trial testimony. The attorney needs to have a thorough understanding of the expert's opinions, along with the basis for those opinions, so there are no surprises in the courtroom. The testimony and opinions of the expert, together with the trial exhibits, are presented during the direct examination by the attorney who retained the expert. The expert has the responsibility of clearly and simply explaining the weather elements of the case to the judge or jury. Cross-examination of the expert by the opposing attorney is standard practice. If some points of the testimony need to be clarified following the cross-examination, the attorney who retained the expert has an opportunity to ask additional questions in redirect examination. Once the expert's courtroom testimony is finished, the expert's participation in the litigation usually ends, unless appeals in the matter require a re-hearing of the expert's opinions.

Examples of Meteorological Investigations

A tragic aviation accident, in which weather played a critical role, was the crash of a commercial aircraft, American Eagle flight 4184, near Roselawn, Indiana, on 31 October 1994. The aircraft was in a holding pattern at 3000 m altitude for about 30 minutes while waiting for clearance to land at Chicago's O'Hare airport. Shortly after it was released by air traffic controllers from its holding pattern, it descended toward 2500 m, at which time the pilots could no longer control the aircraft and it crashed into a field, killing all 68 people on board.

Airframe icing can significantly degrade the performance of an aircraft. Based on the findings of detailed meteorological investigations of the Roselawn accident, the cause for the loss of control is strongly suspected to have been the accumulation of a ridge of ice behind the leading edge of the wings. Because the wings of the aircraft operating as Flight 4184 were located at the top of the fuselage, the pilots were unable to see the formation of ice on top of the wings. Relatives of the deceased passengers sued the airline partly over the alleged inaction of the pilots with respect to the hazardous icing conditions. Attorneys in the litigation retained aviation weather experts and much of the meteorological investigation focused on the nature, timing, and severity of the icing conditions. The microphysics of supercooled drizzle drops was an important aspect of the investigation, since the atmospheric conditions were indicative of the presence of such drops in the area of the holding pattern. These drops can be particularly hazardous to aircraft because they can flow over and freeze behind the icing-prevention devices on the leading edge of the wings and create ice formations that seriously disrupt air flow over the wings. Data and images from the National Weather Service Doppler radar near Chicago (see example in [Figure 1](#)) were carefully studied to determine when the aircraft most likely encountered

Figure 1 Track of American Eagle Flight 4184 during part of its holding pattern near Chicago, Illinois, on 31 October 1994, plotted on a National Weather Service Weather Surveillance Radar reflectivity image. Time associated with each aircraft position is in minutes after 21:00 Universal Coordinated Time. The aircraft occasionally encountered areas of light precipitation, most likely supercooled drizzle drops, during its hold.

supercooled drizzle drops during the holding pattern. The meteorological analysis was partly intended to determine whether any early visible indications of icing were present that might have given the crew an opportunity to respond and take evasive action. A substantial amount of time and effort was spent on the preparation of trial exhibits related to the weather testimony, but the litigation was settled shortly before trial.

Commercial and private aircraft are also subject to hazardous weather associated with thunderstorms. The occurrence of microbursts (intense small-scale downbursts in the decaying stages of a thunderstorm) are of particular concern on approach or departure from an airport. Large changes in wind speed and direction across a microburst can create sudden and unexpected changes in lift. The ability of the pilots to recognize and avoid the hazardous conditions associated with a microburst are usually at the center of the litigation in such cases. Microbursts were the primary cause of several major accidents, such as the Delta Air Lines crash at Dallas, Texas, on 2 August 1985 and the US Airways crash at Charlotte, North Carolina, on 2 July 1994. Litigation related to these crashes relied not only on detailed analysis of the meteorological data but on eyewitness statements from pilots of other aircraft and air traffic controllers regarding the weather.

Severe turbulence can cause passenger injuries on commercial flights and such incidents often lead to lawsuits against the airlines operating the flights. Typically the plaintiff will allege that the pilots should have anticipated and avoided the turbulence. Aircraft operation in and around thunderstorms increases the likelihood of a severe turbulence encounter. Avoidance of thunderstorms is made possible through direct visual observation, on-board weather radar, and pre-flight and in-flight weather briefings. Other atmospheric phenomena, such as breaking mountain waves and strong vertical or horizontal shear in jet streams, can also cause severe turbulence, but such conditions are usually more difficult to anticipate and avoid than convective turbulence.

The examination of satellite, radar, and upper-air data is usually a critical component in meteorological investigations of turbulence incidents. Two passengers who allegedly suffered turbulence-related injuries during a flight across the southwestern United States in March 1996 sued the airline. The airline hired an aviation meteorologist who concluded that there was no meteorological evidence for the turbulence encounter. However, the meteorologist working for the plaintiff obtained satellite photographs that showed the existence of strong mountain waves at the time and location of the incident, consistent with the plaintiffs' allegation. The case was settled shortly after the report of the plaintiff's expert was submitted in the litigation.

Sometimes unofficial weather measurements are at least as valuable as official records. The construction of a natural gas pipeline in South America was interrupted by heavy rain and destructive flooding in April 1998. The construction company was insured against losses of this kind and filed a large claim for extensive damage and delay associated with the event. The insurer was uncertain about paying the claim since rainfall totals from official weather stations in the region were not sufficiently large to have caused the flood damage claimed by the construction company. The insured party produced an unofficial measurement of 325 mm of rain in one day from a hotel located near the project. The rainfall reading at the hotel was many times larger than any of the official readings. In order to resolve the validity of the claim, the insurer hired a meteorologist to investigate the weather conditions, as well as forensic civil engineers who inspected the physical damage. An examination of weather satellite data demonstrated that an isolated severe thunderstorm with exceptionally high cloud top heights (Figure 2) did occur along the segment of the pipeline where the most severe damage was found. A range of probable rainfall amounts was inferred from satellite data and was generally consistent with the high rainfall reading at the hotel. Although the heavy rainfall did not cover as much of the pipeline project as claimed by the construction company, the insurer concluded that at least part of the claim was valid.

In another example, the owner of a Florida resort hotel claimed that extensive water damage to the interior of the building was the result of roof leaks during a very heavy rainfall event. The hotel owner filed a lawsuit against a construction company that had repaired the roof shortly before the alleged damage. Attorneys for the construction company retained a forensic meteorologist to determine whether a heavy rainfall event actually occurred at the property during the period in which the water damage occurred. Rain gauges in the area did not confirm the

Figure 2 Color-enhanced infrared satellite image from Geostationary Operational Environmental Satellite 8 on 8 April 1998 at 11:45 Universal Coordinated Time near Puerto Suarez, Bolivia. Lower temperatures indicate higher cloud tops. Note the very cold temperatures for the heavy thunderstorm near the center of the image. Heavy rain from this thunderstorm caused flooding and extensive damage to a pipeline construction project.

occurrence of a rain event of the magnitude alleged by representatives of the hotel. The amounts were far below the quantity of water associated with the interior damage. Attorneys for the hotel asserted that since isolated heavy rainfall often occurs in Florida, the rain gauges simply missed the 'deluge' at the hotel. Examination of data from the National Weather Service Doppler radar station that monitors the region demonstrated conclusively that the rainfall amounts at the hotel were similar to the amounts measured at the rain gauges. The case reached trial and the meteorologist testified about the rainfall and radar analysis. The jury found in favor of the defendant, i.e., the construction company, concluding that it was impossible that rain could have caused the water damage to the interior of the hotel.

The Outlook for Forensic Meteorology

The density and value of physical property is steadily increasing in regions especially susceptible to weather damage, such as coastal areas. While significant improvements are being made in aviation safety procedures, particularly related to the distribution and analysis of weather information for pilots and air traffic controllers, the frequency of air travel is also expected to grow rapidly. Furthermore, judicial systems are generally increasing the monetary value assigned to human life and health. As a result, the amount of litigation related to weather is likely to expand, increasing the need for forensic meteorological services.

With the expectation of additional enhancements in the quality and quantity of data from remote sensors and computer

models of the atmosphere and ocean, the work of the forensic meteorologist will become more complex and require continual upgrades in professional skills and knowledge. On the other hand, advances in observational and analytical techniques will likely also reduce uncertainties regarding past weather conditions and, therefore, enhance the value of meteorological research and testimony with respect to litigation.

Synopsis

The atmospheric general circulation connotes the motion of the atmosphere, as viewed from a global, long-term perspective. This term is usually applied to the seasonally-varying, climatological-mean circulation, including the statistical properties of the variability of the circulation on day-to-day, week-to-week, and month-to-month time scales, but it also encompasses year-to-year variability and long-term variations associated with climate change. A unifying concept in studies of the general circulation are the so-called balance requirements for the conservation of angular momentum, total energy, and the mass of water vapor and other trace substances. Also of interest are the processes that contribute to the generation and dissipation of the kinetic energy, the exchange of kinetic energy between the zonally averaged circulation and the longitudinally varying 'eddy', the exchange of air between troposphere and stratosphere, and the long range transport of trace substances.

The atmospheric general circulation encompasses the planetary-scale wind systems that shape the Earth's climate. Features of interest include the belts of midlatitude westerlies and subtropical trade winds at the Earth's surface, the jet streams aloft, and the storm tracks. Most of these features are apparent in the figures discussed in this article. They are summarized in the schematic in [Figure 1](#).

The general circulation can be partitioned into zonally symmetric and eddy components, where 'zonally symmetric' denotes longitudinally (*zonally*) averaged (i.e., averaged around latitude circles) and 'eddy' denotes departures from the zonal average. By construction, the zonally symmetric flow is a function of latitude and height only. Certain properties of the eddies, such as the root mean squared amplitude of the eddies in various fields, can also be zonally averaged and displayed in the form of two-dimensional (latitude vs height) cross sections. Understanding the climatology of such zonally averaged fields is one of the principal goals of general circulation research.

[Figure 2](#) shows the zonally symmetric component of the zonal wind and temperature fields for (1) December through

February (DJF) and (2) June through August (JJA). At the Earth's surface, westward (i.e., east to west) 'trade winds' prevail equatorward of 30° latitude, while eastward wind prevails at higher latitudes. The eastward winds strengthen with height and reach a peak at the 10 km level just poleward of 30° latitude in both hemispheres. These zonal wind maxima commonly referred to as the 'tropospheric jet streams' lie along the boundary between troposphere and stratosphere. Dry, ozone-rich stratospheric air is found above and poleward of the tropospheric jet streams; moist, ozone-poor tropospheric air is found below and equatorward of them. Tropospheric and stratospheric air can also be distinguished in [Figure 2](#) by the marked difference in lapse rate, which determines the vertical spacing between the isotherms.

The jet streams are strongest during winter, when the north-south temperature gradient in the troposphere is strongest. The even stronger so-called polar night jet is observed in the middle and upper stratosphere of the winter hemisphere, separating the cold, dark polar cap region from the less cold sunlit portion of the hemisphere. The Southern Hemisphere

polar night jet is much stronger than its Northern Hemisphere counterpart.

Figure 3 shows the zonally averaged mean meridional (i.e., north/south) circulations for the same seasons as Figure 2 and for the annual mean. The trade wind belt is characterized by equatorward flow at the Earth's surface; the belt of surface eastward winds at higher latitudes is characterized by poleward flow. The low-level meridional flows constitute the lower branches of closed circulation cells extending through the depth of the troposphere. By far the strongest of these cells is the tropical 'Hadley cell,' whose rising branch delineates the belt of heaviest tropical rainfall and whose sinking branch is closely associated with the desert regions. Weaker 'Ferrel cells' in which air circulates in the opposite sense to the Hadley cell, are discernible in midlatitudes.

The rising branch of the Hadley cell is located at tropical latitudes in the summer hemisphere, while the sinking branch is located at cooler subtropical latitudes in the winter hemisphere. Circulations such as the Hadley cell are said to be 'thermally direct' or 'thermally driven,' since they are characterized by the rising of warmer air and the sinking of cooler air, as in convective cells. In contrast, circulations like the Ferrel cell are said to be 'thermally indirect' or 'thermally damped.' They are marked instead by the rising of air in cooler regions and the sinking of air in warmer regions.

In the tropics, the mean meridional circulation is strongly seasonally dependent and straddles the equator during the solstitial seasons DJF and JJA. However, when the data are averaged over the whole year, a different pattern emerges with rising motion near the equator, poleward flow in the upper

Figure 3 Pole-to-pole cross sections showing zonally averaged and time-averaged mean meridional circulations for the seasons December through February (DJF) and June through August (JJA), and for the calendar year (Year). Based on the ERA-Interim Reanalyses. © Elsevier.

troposphere, sinking motion in the subtropics and equatorward flow in the trade wind belts just above the Earth's surface.

The circulation cells pictured in Figure 3 represent time averages and zonal averages of wind measurements taken at fixed points in space. The circulation patterns derived from such measurements are said to be 'Eulerian mean circulations.' Composites of the trajectories of numerous individual air parcels, averaged over longitude and over an extended period of time give a different impression of the mean meridional circulations. As viewed from this so-called Lagrangian perspective, the Hadley circulations extend into high latitudes and the midlatitude Ferrel cells virtually disappear, as indicated on the lower right quadrant of Figure 1.

Balance Requirements

The general circulation must satisfy a number of so-called balance requirements relating to fundamental conservation laws. The balance requirements can be posed as a series of statements that for any specified region (e.g., the tropics or the Arctic polar cap region), the imports, exports, sources, and sinks of any given conserved quantity must sum to zero when averaged over a sufficiently long time. For the atmosphere as a whole, in the absence of long-term trends, sources must equal sinks.

Kinetic Energy

Frictional dissipation observed within the planetary boundary layer and within patches of turbulence within the free atmosphere is continually depleting the kinetic energy of planetary-scale wind systems. Half the energy would be gone within a matter of days were there not some mechanism continually operating to restore it. The source of this kinetic energy is the 'available potential energy (APE)' inherent in the distribution of atmospheric mass. The size of the APE reservoir depends upon the height of the atmosphere's center of mass relative to mean sea-level. APE is released whenever the center of mass is lowered through the sinking of colder, denser air and the rising of warmer, less dense air in thermally direct circulations like the Hadley cell. Such circulations also act to flatten out the potential temperature surfaces, thereby weakening existing horizontal temperature gradients on pressure surfaces.

The kinetic energy released by such large scale, thermally direct circulations is imparted not to the vertical component of the motion, which is so small as to be inconsequential with respect to kinetic energy, but directly to the horizontal component of the flow, which is pushed across the isobars from higher to lower pressure by the horizontal pressure gradient force. Such cross-isobar flow toward lower pressure is particularly strong close to the Earth's surface, where the dissipation of kinetic energy is most intense. For example, the trade winds in the lower branch of the Hadley cell (Figures 1 and 3) exhibit a component directed down the pressure gradient, out of the subtropical high-pressure belt and into the belt of low pressure that coincides with the rising branch of the Hadley cell in equatorial latitudes. The poleward flow in the upper branch of the Hadley cell is also down the pressure gradient, as evidenced by the existence of eastward winds at

that level, which implies (from the geostrophic wind equation) that pressure decreases with latitude.

Thermally direct circulations like the Hadley cell that are characterized by the rising of warmer, lighter air and the prevalence of cross-isobar horizontal flow toward lower pressure, thus release APE and convert it to the kinetic energy of the horizontal flow. Thermally indirect circulations like the Ferrel cell can be viewed as 'mechanically forced,' and cycle energy in the opposite direction. In the absence of diabatic heating and friction, the sum of the available potential and kinetic energy is conserved: for example, for a thermally direct circulation, the APE released is equal to the kinetic energy generated.

For the atmosphere as a whole, thermally direct circulations are prevalent. Since thermally direct circulations are continually depleting the atmosphere's reservoir of APE reservoir, something must be operating to restore it. Heating of the atmosphere by radiative transfer and by the release of the latent heat of condensation of water vapor in clouds acts to restore the APE in two ways: (1) by warming the atmosphere in the tropics (where the sum of the condensation heating and the absorption of incoming solar radiation exceeds outgoing infrared radiation) and cooling it at higher latitudes, where the reverse is true; and (2) by heating the air in the lower and middle troposphere, where most of the condensation heating takes place, and cooling it at higher levels, where infrared cooling to space prevails.

Mechanism (1) acts to maintain the equator-to-pole temperature contrast on pressure surfaces. Mechanism (2) acts to expand the air in the lower troposphere and compress the air in the upper troposphere, thereby lifting the air at intermediate levels, which acts to maintain the height of the atmosphere's center of mass against the lowering produced by thermally direct circulations. Hence, the maintenance of the atmospheric general circulation requires both horizontal and vertical heating gradients.

The above can be summarized in terms of a 'kinetic energy cycle' as depicted in Figure 4, with generation of APE (G) by diabatic heating, conversion of APE to kinetic energy (C) by thermally direct circulations, and the dissipation of kinetic energy (D). In the long-term mean, for the atmosphere as a whole, the rate of dissipation of kinetic energy is sufficient to deplete the global reservoir of kinetic energy in only about a week. If APE as well as kinetic energy is taken into account, the timescale for depleting (or recharging) the system is on the order of a month.

Angular Momentum

The angular momentum of an air parcel is given by $(\Omega R \cos \varphi + u)R \cos \varphi \, dm$, where Ω is the angular velocity of

Figure 4 Kinetic energy cycle showing the reservoirs of available potential energy (A), and kinetic energy (K), the generation of available potential energy by horizontal gradients of diabatic heating (G), the conversion of available potential energy to kinetic energy in thermally direct circulations (C), and the frictional dissipation (D). © Elsevier.

the Earth's rotation, R is the radius of the Earth, ϕ is the latitude, and dm is the mass of the air parcel. Apart from small tidal interactions with the Moon, the total angular momentum of the atmosphere plus oceans plus solid Earth is conserved. Despite its enormous mass, the angular momentum of the ocean is very small, owing to the inhibition of circumpolar currents by the continents. Hence, whenever the atmosphere gains angular momentum it tends to be at the expense of the solid Earth, and vice versa. A strong correlation between length of day and atmospheric angular momentum is, in fact, observed on timescales ranging from days up to a few years. On longer timescales, slow motions within the Earth's molten core also affect the length of day.

Eastward winds circulate around the Earth's axis in the same sense as the Earth's rotation. Hence, air parcels in the atmosphere's eastward wind belts rotate more rapidly than the solid Earth does, and air parcels in westward wind belts rotate more slowly. It follows that the frictional drag that is acting to slow the tropical trade winds has the effect of transferring angular momentum from the solid Earth to the atmosphere. In a similar manner, frictional drag on the surface eastward flow that prevails poleward of 30° latitude transfers angular momentum from the atmosphere back to the solid Earth.

The torques (force times distance from the Earth's axis) that the atmosphere exerts upon the solid Earth by virtue of the atmospheric pressure difference between the east and west slopes of large, north-south oriented mountain ranges like the Rockies and Andes also transfer angular momentum between the atmosphere and solid Earth. This effect tends to be of the same sign as the frictional torques on the surface winds. Hence, there exists a balance requirement for a poleward transport of angular momentum within the atmosphere. The transport must be largest near 30° latitude, which marks the transition between the tropical trade winds and the eastward surface flow at midlatitudes, as depicted in Figure 2.

Angular momentum can be transported poleward across a latitude circle by either (1) a systematic poleward flux of atmospheric mass, or (2) 'exchange processes' in which poleward-moving air parcels carry more angular momentum (i.e., have a stronger eastward wind component) than equatorward-moving parcels. The net mass flux in the Earth's atmosphere is very small, as evidenced by the fact that mean

surface pressure over the region poleward of 30° latitude is not systematically changing with time. Additionally, there are no appreciable internal sources and sinks of atmospheric mass other than water vapor, which accounts for too small a fraction of the mass of the atmosphere to yield an appreciable transport. Hence, exchange processes must be responsible for the poleward transport of angular momentum.

The exchange processes, in turn, may be divided into two kinds: (1) those involving the Eulerian mean meridional circulations pictured in Figure 3 (and depicted in the upper right quadrant of Figure 1); and (2) those involving the eddies, as depicted in the upper left quadrant of Figure 1. In the annual average, 30° latitude coincides with the boundary between the Hadley and Ferrel cells. Hence, the mean meridional motions cannot contribute to the required poleward transport across that latitude: the eddies must play a key role in fluxing angular momentum from tropical to extratropical latitudes.

The distribution of the northward flux of eastward momentum by the eddies is shown in Figure 5. As inferred above, the eddies do, in fact, exhibit a systematic poleward transport of angular momentum across 30° . The flux is just enough to satisfy the balance requirement inferred from the frictional torques on the surface winds and the mountain torques. To accomplish the required transport, the horizontal flow in the eddies must exhibit a north-south tilt, as pictured in Figure 6. Such a tilt is widely observed in the atmospheric eddies.

It is evident from Figure 5 that most of the poleward transport of angular momentum takes place around the jet stream (~ 10 km) level, where the amplitude of the eddies is largest and the eastward tilt with increasing latitude is most pronounced. The Hadley cell is instrumental in transporting the angular momentum acquired by the trade winds upward to the jet stream level. The air in its rising (equatorial) branch contains much more angular momentum per unit mass than the air in its sinking (subtropical) branch due to its larger distance from the Earth's axis of rotation. The vertical exchange of air parcels of equal mass, but containing differing amounts of angular momentum per unit mass results in a net upward transport of angular momentum in the Hadley cell. In a similar manner, the Ferrel cell is instrumental in transporting eastward angular momentum downward from the jet stream level to the

Figure 5 Annual mean northward flux of eastward momentum due to the horizontal motions in eddies, expressed in units of $\text{m}^2 \text{s}^{-2}$ (i.e., per unit mass and per unit length of the latitude circle). Based on the ERA-Interim Reanalyses. © Elsevier.

Figure 6 Idealized sketch showing the relationship between the tilt of the eddies and the poleward transport of eastward momentum. In order for poleward-moving air to have a stronger eastward wind component than the equatorward return flow, the eddies must have a southwest–northeast tilt, as shown. © Elsevier.

surface where it is lost to the solid Earth via frictional and mountain torques. The resulting upward/poleward/downward transport of angular momentum is depicted in the upper left quadrant of [Figure 1](#).

Total Energy

Averaged over the year, the net radiation at the top of the atmosphere is downward at low latitudes and upward at high latitudes. These local imbalances reflect the differing meridional profiles of insolation (incoming solar radiation) and outgoing terrestrial radiation pictured in [Figure 7](#). The former slopes steeply downward toward the poles, reflecting the strong latitudinal dependence of solar zenith angle. The latter mirrors the more gently sloping profile of the infrared radiation emitted to space from clear air, cloud tops, and the underlying surface. Since the equator-to-pole temperature gradient is not observed to be increasing systematically with time, these local imbalances must be fully compensated by the poleward transport of energy from the low latitude ‘surplus’ region to

Figure 7 Annual mean net incoming solar radiation and outgoing terrestrial radiation as a function of latitude, expressed in units of W m^{-2} . Distance on the latitude scale is proportional to area on the Earth’s surface. From Wallace, J.M., Hobbs, P.V., 2006. *Atmospheric Science: An Introductory Survey*, second ed. Elsevier, 483pp.

the high latitude ‘deficit’ region, as depicted in the lower left quadrant of [Figure 1](#). The transport must be largest in midlatitudes where the curves in [Figure 7](#) cross one another.

The atmosphere and oceans both contribute to the poleward transport of energy. In both media, the transport involves exchange processes, with poleward-moving fluid parcels carrying larger amounts of total energy than equatorward-moving parcels by virtue of their having recently been heated while residing at low latitudes. In the ocean, both the shallow, wind-driven gyre circulations and the deeper thermohaline circulation contribute to the transport of energy: the gyres by transporting warm water poleward in the western boundary currents and cooler water equatorward on the eastern side of the oceans; the thermohaline circulation by transporting relatively warm surface water poleward and cold bottom water equatorward, primarily in the North Atlantic.

In the atmosphere, much of the total required transport is accomplished by eddies, in which poleward-moving air parcels carry with them greater amounts of sensible and latent heat than do equatorward-moving parcels. The thermally indirect Ferrel circulation does not transport energy poleward across middle latitudes: when the gravitational potential energy of air parcels is taken into account as well as the latent and sensible heat, the equatorward-moving air parcels in the upper branch of the Ferrel cell carry with them more energy per unit mass than the warmer, more moist poleward-moving parcels in its lower branch.

Eastward-moving baroclinic waves, such as that depicted in [Figure 8](#), are responsible for most of the poleward eddy transport of sensible and latent heat across middle latitudes. These waves derive their energy from the prevailing north–south temperature gradient (*see Dynamical Meteorology: Baroclinic Instability*). At the Earth’s surface, they are marked by intensifying cyclones (gyres that circulate in the same sense as the Earth’s rotation) attended by sharp frontal boundaries that separate warm, poleward-moving air masses on the cyclones’ eastern flanks from cold, equatorward-moving air masses on their western flanks ([Figure 8](#)). The meridional displacements of warm and cold air masses in the waves serve to sharpen the east–west temperature gradients. Meanwhile, the rising of the poleward-flowing warm air masses, in combination with the sinking of the equatorward-flowing cold air masses, serves to release APE, providing the kinetic energy needed to amplify the waves. Baroclinic waves tilt westward with increasing height: the wave troughs in the pressure field at the 5 km level overlie the cold air masses at the Earth’s surface.

In the Northern Hemisphere wintertime, planetary-scale stationary waves (sometimes also referred to in the general circulation literature as ‘standing eddies’) forced by the large thermal contrasts between the cold continents and the warmer oceans and by the blocking effect of the Rockies and the Himalayas also make an appreciable contribution to the poleward transport of sensible heat (*see Dynamical Meteorology: Stationary Waves (Orographic and Thermally Forced)*). The Icelandic and Aleutian lows are prominent stationary wave features in the wintertime mean sea-level pressure pattern. Poleward flow to the east of these low-level cyclones carries warm air northward, keeping western Europe and coastal southeast Alaska relatively warm compared to other regions at the same latitude, and the

Figure 8 Synoptic charts at 12 h intervals in an amplifying baroclinic wave passing over the Central United States 10 November 1998. equatorward flow of cold air to the west of them contributes to the coldness of Siberia and eastern Canada. The Northern Hemisphere wintertime stationary waves tilt westward with height and they extend upward into the stratosphere. The poleward heat transport by the eddies peaks in midlatitudes and in the lower troposphere, as shown in Figure 9 and in the lower left quadrant of Figure 1.

Water Vapor

The mass of water vapor in the atmosphere is not changing appreciably on timescales comparable to the residence time of individual water vapor molecules in the atmosphere, which is only about a week. Hence, for the globe as a whole, a balance between evaporation and precipitation is required on timescales of a week or longer. However, on a regional basis there can be large imbalances between evaporation and precipitation due to the import or export of atmospheric water vapor by large-scale wind systems. Precipitation exceeds evaporation by a factor of two or more in the equatorial rain belts and in the midlatitude storm tracks and an imbalance in the opposite sense prevails in the subtropical deserts and cloud-free

maritime anticyclones. These features are highlighted in Figure 10, which also indicates the directions of the required atmospheric water vapor transports. The eddies are responsible for most of the poleward transport of water vapor from the subtropical dry zones into the midlatitude storm tracks, while the steadier trade winds that constitute the lower branch of the Hadley cell are responsible for most of the equatorward transport into the tropical rain belts, as depicted in Figure 1.

Regional imbalances between evaporation and precipitation also have implications for the oceanic thermohaline circulation. Excess precipitation freshens the surface waters, decreasing their density and thereby rendering them more stably stratified. The impact of the atmospheric hydrological cycle upon the oceanic circulation is particularly important in the regions of bottom water formation over the North Atlantic Ocean and the Weddell Sea.

The remarkable dryness of the lower stratosphere is a consequence of the Lagrangian mean, so-called *Brewer–Dobson* circulation, in which air parcels enter the stratosphere through the very cold tropical ‘tropopause’ (Figure 2), move poleward and eventually reenter the troposphere at higher latitudes, often in discrete intrusions in the vicinity of the jet stream. The

Figure 9 Annual mean northward heat flux due to the horizontal motions in eddies, expressed in units of Km s^{-1} (i.e., per unit mass and per unit length of the latitude circle). same circulation carries ozone poleward and downward from its photochemical source region in low latitudes around the 30 km level to its principal reservoir in the 10–20 km layer in high latitudes.

What Determines the Character of the General Circulation?

To understand why the observed planetary-scale wind systems have the particular geographical and seasonal dependence and amplitude that they do, scientists rely upon experience gained from working with numerical models based on the conservation laws that pose the balance requirements considered in the previous section. When such a model atmosphere is ‘turned on,’ starting from a state of rest (i.e., stable stratification, a horizontally uniform temperature distribution, flat pressure surfaces, and no wind) the tropics warm and the polar regions cool in response to the imposed distribution of radiative heating, which is designed to mimic that in the real atmosphere. As the tropical atmosphere warms, the thermal expansion of air causes pressure surfaces in the upper troposphere to

bulge upward relative to the cooling air at the higher latitudes, as depicted in [Figure 11\(a\)](#). The downward sloping of the pressure surfaces from equator to pole gives rise to a poleward flow at the upper levels as depicted in the figure. The poleward mass flux causes mass to accumulate and sea-level pressure to rise at high latitudes, driving a compensating, equatorward low-level flow. Hence, the initial response to the heating gradient is the development of a thermally direct circulation reminiscent of the Hadley cell, but extending all the way from equator to pole, as shown in [Figure 11\(b\)](#). The conservation of angular momentum imparts a westward component to the equatorward flow in the lower branch of the cell and an eastward component to the poleward flow in the upper branch. The vertical wind shear between the low-level westward flow and the upper-level eastward flow increases in proportion to the strengthening north–south temperature gradient, in accordance with thermal wind balance ([Figure 11\(c\)](#)).

For a few weeks of simulated time this equator-to-pole thermally direct circulation persists and the upper-level eastward winds and the meridional temperature gradient continue to strengthen. Up to this point, the circulation is zonally symmetric. But when the temperature gradient reaches a critical

Figure 11 Schematic depiction of the general circulation as it develops from a state of rest on an idealized ocean covered but otherwise ‘Earthlike’ planet under equinox conditions. threshold value for *baroclinic instability*, the simulated circulation undergoes a fundamental reorganization. Successive generations of baroclinic waves spontaneously develop, amplify, and decay in the manner shown in [Figure 8](#). As they do so, they modify the general circulation as indicated in [Figure 11\(d\)](#). As the waves amplify, they produce large poleward eddy heat fluxes that oppose the further buildup of the meridional temperature gradient across midlatitudes. As they disperse upward toward the jet stream (10 km) level and thence equatorward into the tropics, they are attended by a poleward flux of angular momentum from the tropics into midlatitudes. The wave-induced heat and momentum fluxes give rise to the observed thermally indirect midlatitude Ferrel cell ([Figures 1 and 3](#)), which maintains the surface westerlies against frictional dissipation. Were it not for the baroclinic waves, there would be no Ferrel cell, and the broad belt of surface westerlies poleward of 30° would not exist.

Beyond the Zonally Averaged General Circulation

The zonally averaged diagnostics considered in the foregoing sections deal with only the broad outlines of the general circulation: they leave many important zonally varying features unaccounted for, particularly in the Northern Hemisphere where the orography and land/sea thermal contrast are most pronounced. For example, it is evident from [Figure 12](#) that the eastward wind maximum near 30° N in [Figure 2\(a\)](#) is a composite made up of intense wintertime jets over Japan and the eastern United States, as contrasted against more diffuse westerlies over other parts of the hemisphere. In a similar manner, the eddy flux cross sections presented in [Figures 5 and 9](#) tend to be dominated in the Northern Hemisphere by well-defined ‘storm tracks’ over the oceans downstream of the continents. Understanding the zonally varying structure of the general circulation requires consideration of more complex,

three-dimensional balance requirements and numerical simulations that incorporate careful treatment of land–sea thermal contrasts and mountains.

Nor can the statistics that describe the general circulation necessarily be regarded as perfectly reproducible, year after year. For example, they are discernibly different during contrasting years of the El Niño/Southern Oscillation cycle, particularly over the Pacific sector during the months of December through March. They may also occur in response to changes in the distribution of radiative heating brought about by anthropogenic emissions of radiatively active trace gases and aerosols.

Synopsis

Variability in the angular momentum of the atmosphere, related to wind and mass, mirror climate and weather fluctuations. Important signals derive from the strength of the subtropical upper-level jets. Notable variability occurs on diurnal, sub-seasonal, annual, semiannual, interannual, and decadal/interdecadal scales, including from the quasi-biennial oscillation and the El Niño Southern Oscillation. Torques against the surface transfer angular momentum by pressure against mountains or by frictional action, related to changes in Earth's rotation, namely length of the day changes pole motion. Observations and models provide evidence for secular increases in angular momentum in both the recent and upcoming centuries.

Introduction

Angular momentum is a property of mass in motion about a given axis, which in a closed domain is conserved. In the context of the atmosphere, angular momentum is a useful parameter for studying dynamics on different temporal and spatial scales. When the reference axis is identified with that of the Earth's figure, which we may call the principal axis, the resulting globally integrated axial angular momentum value, moreover, may be treated as a fundamental index of atmospheric circulation. As such, this parameter mirrors many aspects of the signature of climate and weather. Furthermore, how angular momentum is exchanged across the atmosphere's lower boundary, by means of the interactive torques with the oceans and solid Earth below, is important to quantify so that one can understand how the Earth acts as a system. Small but measurable changes in the Earth's rotation rate, moreover, are a consequence of the exchanges of angular momentum between the solid Earth and its fluid envelope; this aspect of the variability is of importance to the study of Earth's physics and to the monitoring of reference frames for satellite orbits and navigation. The relevance of atmospheric angular momentum fluctuations to geodesy and geophysics has been recognized by the formal organization of the Special Bureau for the Atmosphere of the International Earth Rotation and Reference Systems Service to supply such atmospheric data to geoscientists.

The angular momentum of a parcel of air in the plane perpendicular to an axis is given as its mass multiplied by the length of the radius arm to the reference axis, multiplied by the component of the velocity of the parcel in that plane, normal to the radius arm. The angular momentum of the global atmosphere about such an axis is the sum of that of all its air parcels, which may be calculated by integration over the volume of the atmosphere. Because the atmosphere is a fluid, variations in its angular momentum relate to changes in both motion terms (relative to the Earth), as well as to changes in its mass distribution.

As a conservative property, angular momentum in a closed system has constant total but can be redistributed within that system. For example, the atmosphere transfers angular momentum poleward in both hemispheres principally by means of transient eddies. Poleward transfers of mass however

mean decreased axial angular momentum because the mass moves to a smaller radius arm from the Earth's axis of rotation. If there are no interactions with the solid Earth, a Coriolis torque will ensue, acting to increase the zonal winds, and keep the angular momentum constant. The transport of angular momentum is also accomplished vertically, carrying angular momentum as part of the Hadley and other mean meridional circulations.

The atmosphere, however, is far from a closed system in this respect, and a stream function/divergence analysis of zonal mean angular momentum reveals sources and sinks at the atmosphere's lower boundary. Indeed, there are exports and imports of angular momentum across the atmosphere's lower interface by means of torques. But the whole Earth, including its fluid components, functions essentially as a closed system with respect to the angular momentum budget (but for the influence of certain well-known tides, principally involving the moon).

If we consider atmospheric angular momentum about the fundamental axis, the relative angular momentum is largely dependent on the westerly component of the wind, with the portion related to mass changes rotating with the Earth very small. Because of the variations in the axial atmospheric angular momentum quantity, the angular momentum in the other components of the Earth's system must change in compensation. Indeed, observations using a number of space-geodetic techniques have demonstrated that the Earth's rotation rate changes perceptibly on many timescales. Such a change is most conveniently expressed in terms of variations in the length of day (l.o.d.), which are very nearly proportional to those in atmospheric angular momentum.

Besides the principal axis, angular momentum may be calculated as well about pairs of other axes in the plane perpendicular to the principal axis, intersecting the equator. In the components in these equatorial axes, the term related to the mass of the atmosphere dominates. These changes of atmospheric angular momentum lead to motions of the Earth's pole about the mean rotation axis – the wobble of the Earth. Such polar motions have also been measured by several space-geodetic techniques.

Changes in the angular momentum of a body must be produced by an imposed torque. In the case of the atmosphere, such interactions occur across its lower interface, with the solid

Earth and the ocean below. These torques are related principally to two mechanisms. In one, surface winds transfer angular momentum by tangential stresses across that surface, yielding a so-called friction torque on the Earth. A second mechanism comes as a result of the existence of surface pressure variability near areas of high topography. Such 'mountain' torques result from the variability of the normal pressure-gradient forces that push harder on one side of the mountain than they do on the other.

In the following, we will examine the distribution of angular momentum in the atmosphere, principally the axial component, and then we discuss its variability on a number of timescales. We also expand upon the relationship to the corresponding motions of the Earth.

Axial Angular Momentum in Regions

The dominant relative angular momentum about Earth's axis depends on the strength of zonal winds, which tend to be persistent features of the atmospheric circulation. In **Figure 1** we present the latitude–pressure distribution of the long-term zonal mean zonal wind based on fields from the reanalysis dataset from the U.S. National Centers for Environmental Prediction and National Center for Atmospheric Research (NCEP–NCAR); we used a 30-year period at the end of the twentieth century to form a climatology of the mean zonal wind. A similar signature exists in the two hemispheres. Mean easterly winds are found in the tropical regions, with a broader latitudinal extent at the surface than higher in the troposphere. The winds are westerly over most of the extratropics. Increases in the strength of these winds with height in the atmosphere lead to very strong westerlies in the upper troposphere, at levels near 200 hPa; above this jet level, they tend to decrease again. Regional maps of such jets at this level reveal that the strongest values are located over the eastern North American and Asian

continents. The strong winds at these regions contribute heavily to the relative component of the axial angular momentum of the atmosphere.

Angular momentum can be computed in zonal belts from values of the zonal wind, so that a profile of angular momentum (**Figure 2**) reveals the general distribution with latitude. The seasonality of the angular momentum can be noted as the substantial difference between the December–January–February periods and the June–July–August periods. It is clear that middle latitude belts have their largest values during their winter, in both the Southern and Northern Hemispheres, but the annual cycle is larger in the northern than in the southern hemispheric belts. Most of the atmosphere has westerly relative angular momentum, indicating that in these regions the atmosphere superrotates with respect to the underlying planet.

Global Atmospheric Angular Momentum

From series of the four-times daily zonal winds given based on the NCEP–NCAR reanalyses, global values of the relative atmospheric angular momentum are calculated by integration over the volume of the atmosphere. In the resulting series of atmospheric angular momentum values, shown in **Figure 3**, a host of interesting signals on a number of important time-scales emerges. For example, it is clear that a strong annual cycle exists, whose phase yields a peak around January, during the period of the strongest Northern Hemisphere jets in the boreal winter. The angular momentum signal in each hemisphere peaks in its respective winter months, but the annual signal in the Northern Hemisphere is of stronger amplitude than that of the Southern Hemisphere, due to the greater continentality of the Northern Hemisphere. As a result, the phase of the global signal is that of the Northern Hemisphere, though the amplitude is reduced. Remarkably, a factor of two exists between the

Figure 1 Latitude–pressure cross-section of zonal-mean zonal winds, from which relative atmospheric angular momentum is derived. Based on 30 years of the NCEP–NCAR analysis system. Units are meter per second.

Figure 2 Long-term mean angular momentum distribution in a set of 46 equal area belts spanning a 30-year time period. Shown are values for all months, for December–January–February and June–July–August months. Units are $10^{24} \text{ kg m}^2 \text{ s}^{-1}$.

Figure 3 Series over 30 years, of globally integrated atmospheric angular momentum between the 1000 and 10 hPa levels, based on the NCEP–NCAR reanalyses. Units are $10^{25} \text{ kg m}^2 \text{ s}^{-1}$.

relative angular momentum values in Northern Hemisphere winter and summer.

In the figure there is also evidence of a superimposed semiannual signal, which can be noted as a combination of a dip during the middle of the northern winter, and a sharp plunge in the middle of the southern winter. This semiannual signal arises largely from the corresponding wind signal in the stratosphere. Such an overall signature is derived from annual patterns at different latitudes that peak 6 months out of phase. These varying patterns can be noted in the time–latitude diagram of angular momentum in the stratosphere in [Figure 4](#).

On interannual timescales, we find two prominent signals in the global signature in [Figure 3](#), one on scales slightly longer than 2 years, and a second on timescales closer to 4 years.

The shorter of the two relates to the so-called ‘quasi-biennial oscillation,’ a result of the reversal of the zonal winds in the tropical stratosphere. The second of the two has a signature that attains a maximum around the time of peaks in the El Niño Southern Oscillation (ENSO) over the tropical Pacific Ocean, and minima at the time of the La Niña events.

Quasi-biennial Oscillation in Atmospheric Angular Momentum and Stratospheric Winds

The distribution of winds in the stratosphere is such that westerly winds predominate in middle latitudes and easterly winds are found in the tropics. In alternate years, approximately,

Figure 4 Time–latitude diagram of angular momentum of the stratosphere in 46 equal area belts, between the 100 and 10 hPa pressure levels. The resolution of data here is monthly. Units are $10^{24} \text{ kg m}^2 \text{ s}^{-1}$.

however, the tropical easterly winds tend to diminish substantially or even reverse their direction to become westerly. Such an alternating signal, though noted first over the western Pacific, has been observed at other longitudes, and it is very well captured by a zonal average. It can be observed in [Figure 4](#) in the 100–10 hPa layer in the stratosphere in the belts surrounding the equator. Because angular momentum is calculated with weights related to the distance to the rotation axis, the contributions from the zonal winds at the lowest latitudes, furthest from the rotation axis, are most important here. The vertical curve on the right hand side of [Figure 4](#), the sum over all the belt values in the stratosphere, clearly reflects an alternation every other year in the global time series of angular momentum in the stratosphere.

ENSO Influence on Angular Momentum

The influence of the ENSO produces a clear signature in the evolution of angular momentum. The origin of the strong peaks in the global relative atmospheric angular momentum may be noted in the time–latitude diagram, such as [Figure 5](#), which, to emphasize the ENSO timescales, filters out signals longer than 4 years and is confined to the region below 100 hPa. During periods of El Niño, the tropospheric zonal winds have westerly anomalies, equivalent to weakened easterlies or to westerlies in part of the tropics initially, and then anomalously strong westerlies more poleward on the order of 0.5–1 year later. During the peak of the westerly anomaly

period, especially, the globally integrated atmospheric angular momentum is notably strong. Two such strong values during this period were during the 1982–83 and the 1997–98 El Niño events. Subsequent events after 1998 have also been noted in records of atmospheric angular momentum. During these episodes, the global signal in relative atmospheric angular momentum was exceptionally high. However, the record value in January 1983 came about as a result of the superposition of the El Niño signal with that of the normally strong seasonal signal during northern winter. With the cooling of the waters in the Pacific, the La Niña ushers in a different circulation from that of the El Niño, and anomalously easterly winds create a negative anomaly in atmospheric angular momentum. The transition can be quite abrupt, as occurred during May 1998, a month that featured a reversal of the sign of angular momentum anomaly across a very wide meridional band from the middle latitude southern to the middle latitudes of the northern hemispheres.

Torques across Atmosphere’s Lower Boundary

The angular momentum of the atmosphere may fluctuate quite rapidly, and so it is apparent that means must exist to accomplish this change at the atmosphere’s lower boundary. Two principal torque mechanisms to effect the angular momentum transfer have been identified. In one, the atmosphere sets up a pressure-gradient force on opposite sides of mountainous topography, and when considered at a distance from the axis,

Figure 6 A comparison of atmospheric angular momentum (AAM) and length of day series, given on equivalent scales. Frequencies with timescales of longer than 4 years have been filtered out. AAM is in units of $10^{26} \text{ kg m}^2 \text{ s}^{-1}$, and length of day in 10^{-3} s .

year 2000. Here, however, data with timescales greater than around 4 years are filtered out, because the Earth's rotation signals at these scales are driven by interactions with the core of the Earth. The very good agreement between the two series is remarkable because of the extremely different data types from which they are derived. The seasonal and intraseasonal fluctuations occur quite closely in both series. Indeed, coherence between the two is very strong on scales down to 7 days, and has some significance on scales as short as daily. Interestingly, intraseasonal fluctuations in l.o.d. were discovered independently from those of the atmospheric Madden–Julian oscillation, related to fluctuations across the Pacific Ocean and observed in both the tropics and extratropics. Differences in angular momentum between the Earth and atmosphere point to either errors in the data sets or to the role in the exchange of angular momentum of a third component such as the oceans.

Models and Historical Series of Atmospheric Angular Momentum

The atmosphere has been simulated by a large number of models that are driven solely by the temperature of the underlying ocean. Based on these models, atmospheric angular momentum has been calculated and used, moreover, as a parameter for model validation to determine the success of model simulations. Aside from observations of angular momentum, independent measurements of l.o.d. have been used to examine the results of models. Lengthy runs of models are possible because sea surface temperatures are available since the latter part of the nineteenth century; these models are unlike atmospheric analyses, whose dependence on upper air winds, are confined to the period since the middle of the twentieth century. Such runs indicate that an increase in such values since that time appear to have occurred, possibly related to the relative increase in El Niño activity. Increases in the short-term variability of atmospheric angular momentum moreover appear to have taken place.

Models can be run in a prognostic mode as well, to determine, for example, the effect of an increase in greenhouse gases on the angular momentum of the Earth. Such effects may include changes in the annual signature, and a possible decrease in angular momentum could be related to the warming of the higher latitudes, which could induce a reduction in temperature gradient and the strength of zonal winds. Use of a coupled atmosphere–ocean models help resolve changes that would be needed for the prediction of angular momentum trends.

Also, because of the close relationship on timescales from days to a few years, between l.o.d. and atmospheric angular momentum, earlier records of l.o.d. have been used as a proxy for the global variations in the atmosphere. A record of l.o.d. back to the dawn of the telescope era in the seventeenth century has been examined, though it is of insufficient accuracy for atmospheric purposes until the end of the nineteenth or the beginning of the twentieth century. Signals relating to changes in variability of the atmosphere during certain decades (like the 1920s and the 1940s, which had high and low interannual variability, respectively, in l.o.d.), and dominant interannual timescales (3.4 and 2.1 years) have been determined from such a proxy record.

Projections into the Future of Atmospheric Angular Momentum

Coupled models of the atmosphere–ocean are used currently to simulate the present state of the atmosphere and to extend the expected state into the future. The Coupled Model Intercomparison Project has organized the running of a number of models throughout the world in different scenarios of the future involving the build-up of greenhouse gases. The results have been used by the Intergovernmental Panel on Climate Change for studying possible effects of greenhouse warming. Possible scenarios include 'business as usual,' extending the rapid growth of CO_2 , as well as more modified scenarios

indicating versions of less rapid growth of greenhouse gases. In general the expectations from these studies are that angular momentum of the atmosphere may increase by some 10% due to changes in the vigor of the zonal winds, particularly in the upper troposphere of both hemispheres in the middle and high latitudes. Three such estimates using the Goddard Institute for Space Studies (GISS) coupled model from the Third Coupled Model Intercomparison Project (CMIP3) archives, out to the year 2100 are given by the increasingly higher curves in **Figure 7** for the increasing amounts of CO_2 that may be put according to these scenarios. Note that results also show the amount of relative angular momentum already increasing from the late 1800s to the present, according to the models and the observations used to construct the angular momentum numbers. Given that the angular momentum of the solid Earth generally decreases with the increasing atmospheric portion, a resulting change in the l.o.d. can extend it by an amount on the order of 0.2 ms.

Atmospheric Angular Momentum on Very Short Timescales

On the other side of the time spectrum from the climate timescales that we just considered here are very rapid changes in the atmospheric angular momentum on the order of several days or less. In fact recent capabilities of models and atmospheric data assimilation systems allow for the calculation of hourly signals. Interestingly, at these timescales, power in the amplitudes of atmospheric angular momentum fluctuations fall quite short of those of the Earth's angular momentum, that is, the Earth's rotation signal, so at these timescales other factors may be in play in the angular momentum balance. Such responses are related to the tides of the atmosphere. Particular peaks in the spectrum of atmospheric angular momentum, shown in **Figure 8**, occur at the diurnal time scale and its next three harmonics (strong semidiurnal, peaks at 8 and 6 h).

Atmospheric Angular Momentum in the Equatorial Plane and Polar Motion

Besides its rotation about the principal axis discussed for most of this article, the other two components of the atmospheric angular momentum vector, namely those in the equatorial plane, can be determined. Though not of clear fundamental

Figure 8 High-frequency spectrum of atmospheric angular momentum based on European Center for Medium Range Weather Forecasts model and analyses during a special observing period in August 2008. The period is given in hours. Note the strong broad annual diurnal period, and also the sharp semidiurnal as well as other peaks in the spectrum. interest to atmospheric studies, this component of angular momentum is related importantly to certain motions of the Earth known as Earth wobble, or polar motion. Related fluctuations of angular momentum in these components are stronger in the so-called matter (surface pressure) term than in the motion (wind) term. Thus, pressure variability over certain regions like the northern Pacific and Atlantic (Aleutian and Icelandic lows, respectively), the southern oceans, and over Eurasia have been determined to be important to fluctuations of equatorial angular momentum (**Figure 9**).

When atmospheric pressure fluctuations over the oceans are observed and carefully accounted for, it has been noted that those on timescales of several days and longer influence the distribution of the ocean mass below. This effect, the so-called inverted barometer, acts so that a high atmospheric pressure will depress the surface below, moving ocean mass away from that region; the opposite action occurs with a relatively low atmospheric pressure. Such an inverted barometer relationship has the affect of dramatically reducing the mass component of the effective angular momentum signal of the atmosphere over the oceans.

For the continental regions remaining, the mass fluctuations over Eurasia, predominantly, and North America, secondarily, appear to be the biggest regional atmospheric influences exciting polar motions on subseasonal and other timescales

Figure 7 Excitations of length of day, proportional to atmospheric angular momentum from the NASA Goddard Institute for Space Studies (GISS) model contributed to the Third Coupled Model Intercomparison Project (CMIP3). Values prior to the year 2000 were based on observations and the underlying model. Those since 2000 are based on three different scenarios of greenhouse gas emissions with the green, blue, and red curves in increasing order of emissions due to economic growth and energy policy.

Figure 9 Variability of (nondimensional) excitation of polar motion, based upon surface pressure analyses for a 30-year period.

which have been monitored using space-geodetic methods. On longer timescales, the ocean plays a role of similar importance to that of the atmosphere. Such more dominant ones for polar motion are the annual term and that of the natural modal response of the Earth's polar motion, with period near 430 days, known as the Chandler wobble. At the other end of the frequency spectrum, a motion of the Earth on near daily timescales, known as nutation, is also driven partially by atmospheric angular momentum forcing.

Energy Cycle

R Grotjahn University of California, Davis, CA, USA

Synopsis

The energy cycle provides a physically meaningful system to understand several constraints upon and properties of the general circulation. Energy is conserved and it can be tracked even as it changes from one form to another. Energy properties can be analyzed to deduce the net circulations as well as the rates at which the circulations are created, maintained, or destroyed.

Introduction

The total energy per unit mass (TE) is defined as:

$$\underbrace{C_p T + gZ + Lq}_{\text{MSE}} + \underbrace{\frac{1}{2}(u^2 + v^2 + w^2)}_{\text{KE}} = \text{TE} \quad [1]$$

where C_p is the specific heat at constant pressure, T the temperature, g the acceleration of gravity, Z the geopotential height, L the latent heat of vaporization or sublimation, q the specific humidity, and (u, v, w) the eastward, northward, and upward wind components, respectively. The terms above are internal energy at constant pressure, gravitational energy, latent energy from phase changes of water, and kinetic energy (KE) per unit mass, respectively. Together the first two terms define dry static energy (DSE) while including the third defines moist static energy (MSE).

The distributions of MSE and DSE in summer and winter seasons are shown in [Figure 1](#). The DSE monotonically increases with height because the large-scale atmosphere is statically stable. DSE decreases toward the poles due to cooler temperatures. The addition of moisture, with most moisture mass in the lower troposphere, causes the vertical derivative of MSE to reverse sign (implying convective potential instability) in the lower tropical troposphere and causes the contours to be nearly vertical in the midlatitude troposphere (the latter indicative of a nearly moist adiabatic lapse rate). In the horizontal, higher values of MSE favor the tropical and summer continents as well as the intertropical and other convergence zones (indicative of low-level moisture convergence). In middle latitudes, lower values of MSE occur on the colder east sides of the continents.

Potential energy (PE) is related to DSE. PE is useful for global energy balance. A tiny fraction of the PE, called the available potential energy (APE), is usable to drive the KE. APE is defined as the difference between the PE and the minimum PE that could be achieved by an adiabatic rearrangement of mass. APE is used to understand the links between PE and KE. Sometimes latent heating is included directly in the APE, usually it is treated as a separate diabatic process.

Solar radiant energy does not reach the Earth equally everywhere. On an annual average, the tropics receive and

absorb far more solar energy than the polar regions. This distribution of absorbed energy creates an uneven distribution of temperature. Temperature, pressure, and density are related, so the PE has an uneven distribution too. The existence of APE is essentially due to the horizontal variations in density and temperature. A portion of the APE is converted into motions (KE) as the atmosphere tries to remove these density and temperature variations. The motions redistribute some mass, but mainly the atmosphere transports heat. The atmospheric circulation becomes a complex balance between radiant energy input and output that create APE, which is needed to generate the KE of circulations that in turn strive to create a state of no APE.

APE and KE are defined in formal mathematical ways. The mathematics show interactions from which physical mechanisms (like baroclinic instability) can be identified. The energy equations describe the following chain of events: radiation creates APE; some APE is converted into motions that redistribute the heat energy; and KE in turn is lost by conversion back to APE and by friction. The forms of energy and the *net* conversions between them can be represented via a 'box' diagram. However, the box diagram does not show the energy cycle in an intuitive sense. To make the physical mechanisms clear, energy must be examined regionally and one phenomenon at a time.

Conceptual Models

Two-Fluid Model

A fluid flow analog of the pendulum illustrates forms and conversions of energy. Imagine a tank holding two immiscible fluids of different densities, separated by a vertical barrier ([Figure 2\(a\)](#)). The initial state has the highest center of mass and thus greatest gravitational PE. If the barrier is suddenly removed, the fluids begin to move. The motion accelerates until the point in time where the greatest amount of the denser fluid underlies the greatest amount of the less dense fluid ([Figure 2\(b\)](#)). The center of mass is now lowest as is the gravitational PE. Ignoring friction, mixing, and turbulent effects, KE is maximized at this point. As time proceeds further, the fluids overshoot this state and KE begins converting back to PE ([Figure 2\(c\)](#)).

Figure 1 Distributions of DSE and MSE during December–February (left column) and June–August (right column) extreme seasons. In (a) and (b), solid lines are MSE while dashed lines are DSE, which differ mainly in the lower and tropical troposphere. In the deep tropics, the vertical gradient of MSE reverses sign from lower to upper troposphere. In (c) and (d), the longitudinal distribution of MSE is illustrated using the pattern at 850 hPa. ERA-40 reanalysis data from 1979 to 2001 used were provided by the European Centre for Medium Range Weather Forecasts.

APE is defined as the difference between the current PE and the minimum PE. The state with lowest PE is the ‘reference state’ having zero APE. The reference state definition is somewhat arbitrary. Another mechanism could possibly occur at some later time to lower further the minimum PE, for example, a net temperature decrease. However, the size of the conversions, generation, and destruction are less arbitrary. APE is intended to represent PE available for driving motions, so the reference state is usually defined by adiabatically rearranging

Figure 2 Schematic model of fluid motion illustrating APE and KE concepts. The tank holds two immiscible fluids with density $\rho_1 < \rho_2$. (a) Initial state; (b) state with maximum KE but minimum PE reached during the first oscillation; and (c) state where KE is being converted back to PE.

atmospheric properties so as to reach a state of minimum PE. This model reveals that density differences across a fixed elevation in the tank are proportional to the APE.

This model relates to the atmosphere as follows:

1. Temperature differences create the density differences. The less dense fluid represents the tropics; the denser fluid represents polar regions.
2. The reference state has minimum center of mass when the air ‘layers’ are flat. However, flat fields of pressure and temperature imply no geostrophic winds and remove a driver for ageostrophic winds.
3. Horizontal density differences (manifest as sloping fluid layers) have APE but also produce horizontal pressure gradients that accelerate the air. On the rotating Earth, geostrophic winds and thus KE are present, too. So, reservoirs, sources, and sinks of APE are not independent of KE.

Carnot Cycle

A Carnot cycle analysis can estimate KE generation from thermodynamic changes that an air parcel undergoes

Figure 3 Interpretation of the Hadley circulation as a Carnot cycle. (a) Meridional cross section showing the idealized circulation. The dashed line shows an average path followed by the parcels with numeric labels for each leg. (b) Skew T-lnP plot of the thermodynamic changes along each of the four legs drawn in part (a). The shaded area is proportional to the energy converted from PE to KE.

while completing an atmospheric circuit. The Hadley cell is a conceptual model for the zonal mean tropical circulation. Air in the lower troposphere moves equatorward while gaining heat and moisture from surface fluxes. Near the equator, rapid ascent within thunderstorms releases and advects much latent heat energy. Reaching the upper troposphere, air moves poleward, cools radiatively, and sinks, completing a circuit.

KE generation can be estimated by plotting the thermodynamic properties of air parcels on a skew T-lnP chart. A unit area anywhere on the chart corresponds to a specific amount of energy exchange. Figure 3 shows a possible circuit around an annual mean Hadley cell. The amount of APE converted into KE by a kilogram of air while it completes the plotted circuit is $E \sim 1.4 \times 10^3 \text{ J kg}^{-1}$.

The rate of energy release per unit horizontal area, R , by all the air in motion can be compared with the rate per unit area of energy absorbed from the Sun.

$$R = ME t^{-1} A^{-1} \quad [2]$$

where M is the mass in motion, t is the time to complete the circuit, and A is the area of the Hadley cell. For the schematic circulation indicated in Figure 3(a), $M \sim 10^{18} \text{ kg}$, $A \sim 10^{14} \text{ m}^2$, and $t \sim 3 \times 10^6 \text{ s}$. The total rate of energy released by the Hadley cell is $ME t^{-1} \sim 5 \times 10^{14} \text{ J s}^{-1}$. However, the rate per unit area is only $R \sim 3.6 \text{ W m}^{-2}$. The absorbed solar radiation in the tropics is 100 times larger than R , making the atmosphere an 'inefficient' heat engine. (Efficiency of the Carnot cycle is often measured in a way dependent on the temperature difference during the cycle, but this estimate is related to energy input.)

The model has the following properties:

1. Warmer air is rising and cooler air is sinking, so the center of mass is lowered and KE is created; the circuit is counterclockwise and the circulation is 'thermally direct'. In contrast, the Ferrel cell is a clockwise circuit that reduces KE to increase PE.

2. A steady state is reached if the frictional losses balance the KE generation.
3. The rate of KE generation depends on the area enclosed by the circuit divided by the time to complete the circuit. That time depends on the speed of parcels, a point reinforced later when the APE to KE conversion term is considered.
4. The amount of energy converted is proportional to a circuit integral of temperature, so it increases as the temperature difference increases between the warm and cold stages of the cycle. During winter the meridional temperature gradient is stronger than summer, and so is the Hadley cell.
5. In winter, the air motion of the Hadley cell is five to seven times stronger than the Ferrel cell, but larger temperature differences occur along the Ferrel circuit. So, the net energy conversions are similar (see Energy Box Diagram section below).
6. Large energies are involved, but only a tiny fraction of the solar radiation actually drives the observed motions.
7. The path followed by air parcels was specified, not predicted.

Available Potential Energy

DSE and therefore PE combine both gravitational and internal energies. To the extent that hydrostatic balance and ideal gas law are valid and working at constant volume, then:

$$\begin{aligned} \text{PE} &= \int_0^\infty \rho g Z dz + \int_0^\infty \rho C_V T dz = \int_0^{P_s} Z dP + \int_0^\infty \rho C_V T dz \\ &= \int_0^\infty \rho (R + C_V) T dz = \int_0^\infty \rho C_P T dz \end{aligned} \quad [3]$$

Figure 4 Zonal mean efficiency factor $[\varepsilon]$ for (a) December–February and (b) June–August. $[\varepsilon]$ is estimated from zonal mean 1979–99 National Center for Environmental Prediction/National Center for Atmospheric Research (NCEP/NCAR) reanalysis data. The contour interval is 0.03.

Hence, gravitational and internal energies are bound together in an R/C_p ratio. APE is approximated by temperature variations on a pressure surface.

$$\text{APE} = \int \varepsilon C_p T dM \approx \frac{1}{2} \kappa C_p P_{00}^{-\kappa} \times \int P^{\kappa-1} \{\theta - \bar{\theta}\}^2 \left(\frac{\partial \theta}{\partial P} \right)^{-1} dM \quad [4]$$

$$\varepsilon = 1 - \left(\frac{P_r}{P} \right)^\kappa \quad [5]$$

M is the mass while other variables are potential temperature θ , $P_{00} = 10^5$ Pa, specific heat at constant pressure C_p , $\kappa = RC_p^{-1}$, ideal gas constant R , and ‘efficiency factor’ ε . $P_r(\theta)$ is the reference pressure: the average pressure on a potential temperature surface θ . APE is zero when $P = P_r$ everywhere in the domain. The overbar denotes the horizontal average on an isobaric surface. APE has the following properties:

1. For an integral over the depth of the atmosphere, APE differs from PE by the factor ε .
2. Observed PE is about a thousand times greater than estimates of global average APE.
3. Hemispheric PE is greater in summer since the air is generally warmer than in winter.
4. Hemispheric APE is greater in winter when the meridional temperature gradient is stronger making the $\{\}$ term larger than in summer. The larger the atmosphere departs from the reference state mean, the larger the magnitude of ε becomes.
5. Diabatic heating or cooling can create APE if it magnifies the departures from the reference state, but the same heating or cooling can destroy APE if it reduces the departures. In simplistic terms, APE is generated by ‘heating where it is hot or cooling where it is cold’.
6. $\varepsilon > 0$ in ‘hot’ regions and $\varepsilon < 0$ in ‘cold’ regions. From **Figure 4**, ε has a positive maximum in the tropical middle troposphere and negative minimums in high latitudes. In middle latitudes, the sign varies with longitude: $\varepsilon > 0$ over oceans during winter or warm sectors of frontal cyclones while $\varepsilon < 0$ over continents in winter or behind cold fronts.

Kinetic Energy

KE is primarily contained in horizontal winds:

$$\text{KE} = \frac{1}{2} (u^2 + v^2) dM \quad [6]$$

KE has the following properties:

1. The distribution of zonal mean KE (**Figure 5**) has maximums at upper levels near the subtropical jets.
2. KE is related to atmospheric momentum and torque. Momentum fluxes by the Hadley cells and by midlatitude eddies maintain the KE maximum near the subtropical jet. Slowing down surface easterlies in the Hadley circulation imparts westerly momentum that is transported to higher latitudes by the upper branch of the Hadley Cell. Eddy momentum flux convergence is another source.

Energy Generation and Conversion

Energy Equations

To understand how energy evolves one needs formulae for APE and KE tendencies in a limited domain. The domain may be a unit area in the meridional plane (useful for calculating zonal means) or enclosing a single phenomenon to the exclusion of others (e.g., a single frontal cyclone). Tendency equations for APE and KE in a mass M between two isobaric surfaces are

$$\begin{aligned} \frac{\partial \text{APE}}{\partial t} = & \underbrace{\int (\varepsilon q) dM}_a + \underbrace{\int (\varepsilon \omega \alpha) dM}_b - \underbrace{\int \varepsilon (\nabla_P \cdot (V_P C_p T)) dM}_c \\ & + \underbrace{\int \left(C_p T \frac{\partial \varepsilon}{\partial t} \right) dM}_d \end{aligned} \quad [7]$$

$$\frac{\partial \text{KE}}{\partial t} = - \underbrace{\int (V_P \cdot F) dM}_a - \underbrace{\int (V_P \cdot \nabla_P \Phi) dM}_b - \underbrace{\int (\nabla_P \cdot (V_P \text{KE})) dM}_c \quad [8]$$

where q contains all diabatic heating and F is the frictional force. Also, ω is the pressure coordinate (‘vertical’) velocity, α is

Figure 5 Zonal mean KE density for (a) December–February and (b) June–August using 1979–99 NCEP/NCAR reanalysis data. The contour interval is $50 \text{ kg s}^{-2} \text{ m}^{-1}$.

the specific volume, Φ is the geopotential, and P subscript indicates evaluation on isobaric surfaces.

The terms are ordered to match similar processes. Term 'a' in each equation has diabatic source/sink mechanisms. Term 'b' is similar but has opposite sign in the APE and KE equations and so represents a (baroclinic) conversion between these two forms of energy. Term 'c' is divergence of PE or KE flux; it is a conversion between the APE or KE inside and that external to the domain; and baroclinic or barotropic conversions, respectively, appear in this term.

Diabatic Sources and Sinks of Energy

There are five categories of diabatic processes: solar and terrestrial radiation, latent and sensible surface heat flux, and friction. **Figure 6** illustrates how diabatic heating is distributed on the seasonal and zonal means.

1. Solar radiation absorbed. Over much of the atmosphere the emission exceeds the absorption (net radiative cooling

(NRC) in **Figure 6**) but in the tropical and summer portions of the stratosphere there is net solar absorption (NRH).

2. Terrestrial radiation emitted. NRC (**Figure 6**) is very strong in the winter high latitudes and subtropics through the depth of the atmosphere. The net cooling is strong in the Southern Hemisphere subtropics in summer. Since emission is stronger from lower (warmer) cloud tops, the net cooling increases toward lower subtropical elevations. While the terrestrial emission ($q < 0$) is greater in the tropics, suggesting destruction of APE, the bulk of the net cooling in the diabatic heating field is in the winter hemisphere. APE is generated because the stronger net emission in high latitudes is from cloud tops where ε is strongly negative. In the less cloudy subtropical latitudes emission mainly occurs where ε has smaller magnitude.
3. Latent heat release. Some solar radiation absorbed by the Earth's surface evaporates water. Evaporation introduces water vapor into the atmosphere, primarily in the subtropics. The latent heat is released some distance away where

Figure 6 Zonal mean heating calculated as a residual in the temperature conservation equation. Areas near zero have no shading. Areas where shading darkens as values become larger in magnitude are negative values (cooling, 'blue' if in color). Areas where shading becomes lighter as values become larger are positive (heating, 'warm colors' if in color). Labels indicate the processes that tend to be larger in given regions. NRC indicates net radiative cooling, NRH means net radiative heating, LH indicates latent heating, SH indicates surface sensible heat flux mixed upward in the boundary layer. Units are Kelvin per day. Reproduced from Källberg, P., Berrisford, P., Hoskins, B., et al. 2005. European Centre for Medium Range Weather Forecasts (ECMWF) ERA-40 Publication 19: The ERA-40 Atlas, 191 pp.

Figure 7 Highly idealized schematic illustration of a midlatitude frontal cyclone during (a) baroclinic growth and (b) baroclinic decay. The 1000 and 200 hPa surfaces are marked. Areas of relatively warmer and colder air at an isobaric level are noted. Double-shafted arrows indicate the relevant part of the ageostrophic circulation. The dot-dashed line in (a) shows the trough axis through the troposphere.

condensation occurs. In the tropics, much latent heat is released in the middle troposphere (mainly in the inter-tropical convergence zone (ICZ)) where $\varepsilon > 0$, hence creating APE. Moisture from the subtropics as well as evaporation over warm waters of an oceanic western boundary current (WBC; e.g., the Gulf Stream) is transported poleward and feeds precipitation in the midlatitude storm tracks. So midlatitude secondary maxima of latent heating occur in the lower and middle troposphere. The midlatitude latent heating is more apparent in summer because the opposing NRC is much stronger in winter. The Asian summer monsoon is seen as a heating maximum near 30° N in Figure 6(b).

4. Surface sensible heat flux. Solar radiation absorbed by the Earth's surface also heats up the ground and that is mixed into the air by turbulent processes. The transfer of sensible heat is large in the subtropics and also near midlatitude WBCs. Generally, the sensible heating is where $\varepsilon > 0$, thereby creating APE. Sensible heating is input into the cold air sector of the extratropical cyclone, thus destroying the temperature contrast between the warm and cold sectors, and so indicating APE destruction. However, sensible heating in the cold sector does lower the static stability, which allows vertical motions to proceed more freely encouraging baroclinic conversion.
5. Friction is only important for KE and it always destroys KE.

Baroclinic Conversions

Terms 'b' in eqns [7] and [8] are similar though opposite in sign, thereby indicating conversion between APE and KE in the limited volume energy equations. Using the hydrostatic and continuity equations:

$$\vec{\nabla}_P \cdot \nabla_P \Phi = \omega \alpha + \nabla_3 \cdot (\vec{\nabla}_3 \Phi) \quad [9]$$

For a closed system, there is no mass divergence and the pressure work term ($\nabla_3 \cdot (\vec{\nabla}_3 \Phi)$) vanishes when integrated over the domain. A large fraction of the wind is described by the geostrophic wind and since the geostrophic wind is proportional to the cross product of Φ , the geostrophic wind does not contribute to the left-hand side of eqn [9]. Hence, ageostrophic motions across geopotential height contours contribute to the left-hand side. For an open system, $\vec{V}_P \cdot \nabla_P \Phi \ll \nabla_3 \cdot (\vec{\nabla}_3 \Phi)$ and so there must be partial cancellation with the $\omega \alpha$ term to have the right-hand side also small. $\vec{V}_3 \Phi$ is a flux of geopotential that

can transport (gravitational) PE into or out of a region. Since $\varepsilon \ll 1$, $\varepsilon \omega \alpha$ has comparable magnitude as $\vec{V}_P \cdot \nabla_P \Phi$.

Two approximate forms of this conversion aid interpretation of the process. For a closed system illustrated in Figure 7, the conversion depends on the difference in thickness above the surface high (H_H) versus above the surface low (H_L):

$$-S g |\omega| (H_H - H_L) \sim \int \vec{V}_P \cdot \nabla_P \Phi \, dM \quad [10]$$

S is the horizontal area for each half of the domain and $|\omega|$ is the magnitude of the mean ω . Since thickness is proportional to the mean temperature of the layer of air, the sign and magnitude of the conversion depend on vertical motion in relatively warmer and colder regions. In Figure 7(a), warm air over the surface low rises while cold air sinks, which means $H_L > H_H$ resulting in cyclogenesis (APE $\rightarrow$ KE). In Figure 7(b), warm air overlies the surface high, so it has greater thickness than the air over the low resulting in cyclolysis. The magnitude of the conversion during the developing stage exceeds that during the decay stage implying net generation of KE.

A simple description of the baroclinic conversion is 'warm air rising or cold air sinking converts APE into KE'. The relationship is seen in the quasigeostrophic system, where

$$-\omega \alpha \approx g \mu w \theta \quad [11]$$

and $\mu \ll 1$ is a nondimensionalizing constant. The Carnot cycle model illustrates this mechanism as does the A_Z to K_Z conversion found in the tropical Hadley cells. (A_Z is the APE constructed from zonal mean quantities and K_Z is the KE constructed from zonal mean winds.)

For the Hadley cell, the integrand of term b in eqn [8] can be approximated by $-[v] \frac{\partial [\Phi]}{\partial y}$ if one neglects zonally varying phenomena like the Asian Monsoon and the Walker Cell. There is no zonal component because the geopotential term is averaged around a latitude circle and identically zero (if no topography is intercepted, i.e., if there is no mountain torque). The low-level flow in the Hadley cell is down the gradient of geopotential (from higher to lower Φ), so the term (including the minus sign) is positive and thereby generating zonal mean KE. For the upper level generally poleward return flow, both the meridional wind and the Φ gradient reverse sign and the KE are being created. Consistently, the rising ($\omega < 0$) branch of the

Figure 8 Zonal mean meridional flux of potential temperature [$v\theta$] for (a) December–February and (b) June–August using 1995–99 NCEP/NCAR reanalysis data. Hadley cell fluxes are apparent in the tropics, while eddy fluxes predominate in midlatitudes.

Hadley cell occurs in the warmer air ($\varepsilon > 0$), so term b in eqn [7] is negative and APE is being lost. Assuming that half the KE conversion takes place in a 300 hPa deep lower layer, moving at 3.5 m s^{-1} , with a geopotential height gradient of 10^{-4} , the full KE conversion in eqn [8] is 2.1 W m^{-2} . The results are consistent with the Carnot cycle calculation and indicate that the KE conversion is small relative to the solar absorption.

In middle latitudes zonally varying phenomena (eddies) dominate the circulation. To drive midlatitude eddies, two conversions are incorporated into the ‘baroclinic’ conversion label: A_Z to A_E and A_E to K_E . In the quasigeostrophic context, the latter is proportional to a vertical eddy heat flux while the former is proportional to a horizontal eddy heat flux. From thermal wind balance, the environment has a meridional temperature gradient and westerly vertical shear. Eddy horizontal heat fluxes are directed down the temperature gradient (toward the pole) if the eddy tilts against the vertical shear. The upstream tilt and vertical heat flux are both visible in the schematic diagram (Figure 7(a)) of cyclogenesis.

Figure 8 shows the observed zonal mean heat flux by all motions. In the tropics the heat flux follows the Hadley cell: lower-level equatorward heat flux and upper-level poleward heat flux. Because MSE is larger at the higher elevation (Figure 1) each Hadley cell has a net poleward heat flux. At higher latitudes heat is advected poleward, mainly in the lower troposphere. The midlatitude eddies have sizable poleward heat flux in the lower troposphere and somewhat less poleward flux in the upper troposphere. The mean meridional (Ferrel) cell circulation opposes the upper troposphere eddy flux and reinforces the lower troposphere eddy flux making the net $[v\theta]$ flux larger in the lower troposphere.

Intra-KE (Barotropic) Conversion

The barotropic conversion rearranges KE. A commonly shown redistribution is between zonal mean and eddy KE. In the KE tendency eqn [8] this conversion (term c) appears as a boundary flux that is zero for a closed domain. The term originates from the horizontal advection terms in the original

component momentum equations and when one derives the conversion between zonal mean and eddy KE then the term is related to eddy momentum flux convergence as well as the mean flow horizontal shear. Zonal mean KE is generated from eddy KE where eddy momentum fluxes are up the gradient of the mean flow.

The eddy momentum fluxes, meridional cells, and jets are linked in the barotropic mechanism. Meridional momentum transport (Figure 9) tends to be largest in the upper troposphere. One reason for this is that midlatitude eddy momentum transport becomes stronger as frontal cyclones reach a mature stage. Momentum transport by the Hadley cell is up the gradient of the zonal mean zonal wind toward the subtropical jet stream; the poleward moving air contains large angular momentum that causes air parcels to accelerate relative to the Earth’s surface. The meridional cells have little meridional motion at the subtropical jet, but the eddies carry momentum further poleward. The Ferrel cell momentum flux opposes the flux by the eddies in the upper troposphere.

Complexity arises from several sources.

1. The eddies have preferred regions of genesis and decay and their momentum fluxes vary greatly between these regions.
2. Mature lows migrate to the cold side of the jet and thus deflect the jet stream equatorward.
3. Eddy momentum fluxes build vertical shear while the eddy heat fluxes reduce the temperature gradient, a combination that destroys thermal wind balance. One consequence is the formation of a secondary circulation, appearing as the ‘Ferrel cell’ on a zonal average, which partially opposes the eddy heat and momentum fluxes. So, the jet streams are equatorward of where the eddy momentum flux has greatest convergence. This Ferrel cell brings westerly momentum downward.
4. The momentum flux convergence in Figure 9 is largest in the winter hemisphere between 30 and 40° N in the upper troposphere. This location of momentum convergence thus seems to be poleward of the subtropical jet. The jet and momentum convergence positions match better if one

Figure 9 Zonal mean meridional flux of zonal wind $[vu]$ for (a) December–February and (b) June–August using 1995–99 NCEP/NCAR reanalysis data. Hadley cell fluxes are apparent in the tropics, while eddy fluxes predominate in midlatitudes.

accounts for the spherical geometry. The zonal component of zonal mean KE tendency is given by eqn [12]:

$$\frac{\partial}{\partial t} \int \left(\frac{[u]^2}{2} \right) dm = - \underbrace{\int [u] \left(\frac{1}{r \cos^2 \varphi} \frac{\partial \{ \cos \varphi \}^2 [uv]}{\partial \varphi} + \frac{\partial [u\omega]}{\partial P} \right) dm}_c + \int f [u] [v] dm - \int [u] [F] dm \quad [12]$$

where r is the radius of the Earth, φ is the latitude, $[\]$ indicates a zonal average, f is the Coriolis parameter, and dm is an increment of atmospheric mass. The subtropical jets have large contribution to the zonal component of KE: $[u]^2$ and the momentum flux $[uv]$ are modified by $\cos(\varphi)$ and $[u]$ factors that shift the larger values of the integrand (term c) to lower latitudes closer to the subtropical jet location.

The eddies need horizontal tilts to accomplish the observed momentum fluxes. **Figure 10** illustrates the southwest to northeast tilts for poleward transport by Northern Hemisphere eddies.

Figure 10 Schematic illustration of how a horizontal tilt of the trough axis (dotted line) leads to a net meridional transport of eddy zonal momentum. Primes denote winds with the zonal average removed. In this case the zonal average eddy momentum flux is northward. In contrast, a low that is symmetric about a north–south axis has $u'v'$ contributions on the east and west sides that cancel in the zonal mean.

Observed Energetics

Global Energy Balance

Ignoring seasonal heating and climatic change heating, there should be a balance between the solar energy absorbed by the Earth and that radiated away to space. The actual energy budget between the Earth and space depends on a variety of factors such as cloud cover, atmospheric composition, and surface properties. Estimates of energy fluxes for the Earth's surface and atmosphere on global and annual averages are presented in **Figure 11**.

Some limitations of this summary depiction are listed below:

1. The balance shown is global, so net radiation is zero. Net radiation (solar minus terrestrial) is positive from 38° N to 38° S and negative elsewhere.
2. Heat fluxes sustain the net radiation pattern; those motions are not included.
3. Vertical fluxes of heat and radiation are not shown, only the net transfer for the whole atmosphere.

Figure 11 Global average energy balance expressed as percentages of the solar radiation striking the top of the atmosphere. Estimates of the solar constant vary, but the 100 units in the figure correspond to $\sim 341 \text{ W m}^{-2}$. Right side: solar radiation processes showing amounts reflected and absorbed. Middle: surface sensible heat flux (wavy arrow) and surface latent heat flux (dashed arrow). Left side: terrestrial radiation processes showing emission, transmission, and absorption. Data in the figure are based primarily on Trenberth, K., Fasullo, J., Kiehl, J., 2009. Earth's global energy budget. *Bulletin of the American Meteorological Society* 90: 311–323.

Figure 12 Zonal and annual average APE (a) of the zonal mean state, A_z , and (b) of the zonally varying state, A_e . Zonal and annual average KE (c) of the zonal mean flow, K_z , and (d) of the zonally varying flow, K_e . The units are $10^5 \text{ J m}^{-2} \text{ bar}^{-1}$. Reproduced from Marques, C., Rocha, A., Corte-Real, J., Castanheira, J., Ferreira, J., Melo-Gonçalves, P., 2009. Global atmospheric energetics from NCEP–Reanalysis 2 and ECMWF–ERA40 Reanalysis. *International Journal of Climatology*, 29: 159–174.

Figure 11 shows the following:

1. At the Earth's orbit, the longwave radiation from the Earth greatly exceeds the longwave radiation from the Sun. So, solar (shortwave) radiation can be treated separately from terrestrial (longwave) energy.
2. The (shortwave) albedo is greatly affected by clouds, which also strongly affect terrestrial emission.
3. More solar radiation is absorbed by the ground (47%) than by the air (23%).
4. The solar radiation reaching the ground evaporates water, is emitted as longwave radiation, or creates a sensible heat flux, in that order of (net) magnitude.
5. The net surface emission must balance the input (18.5 units) not lost by surface fluxes. However, the actual surface longwave emission (116 units) exceeds the shortwave input (47 units) because of downward radiation from the atmosphere, this means the surface temperatures are larger than expected from just the shortwave absorption, an increase known as the 'greenhouse' effect.
6. The average global annual energy absorbed is $\sim 235 \text{ W m}^{-2}$. Multiplied by the Earth's surface area, this is about 121 PW ($1.2 \times 10^{17} \text{ W}$).

The Energy Box Diagram

Since the tropical circulations are dominated by the zonal average Hadley circulation and the midlatitude weather is dominated by the zonally varying frontal cyclones, it is logical to partition the energy into zonal average and zonally varying (eddy) parts. The total APE can be partitioned into zonal average (A_z) and eddy (A_e) parts. Similarly, the total KE is partitioned into zonal average (K_z) and eddy (K_e) parts. These four categories of energy are shown in Figure 12. Zonal average of the APE in the zonal mean fields (Figure 12(a)) is large in the tropics and increases from a subtropical minimum to largest values at

the poles. The zonal average of APE from eddy structures is largest in the middle latitudes (Figure 12(b)). The zonal mean KE of the zonal mean flows (Figure 12(c)) has largest values in the middle latitudes where the major jet streams are found, including the dual jet in the Southern Hemisphere during local winter. The zonal mean KE from eddy motions (Figure 12(d)) is largest in the middle latitudes, with largest values in the upper troposphere. Compared with K_z the distribution of K_e is broader in the vertical and centered at higher latitudes. Comparison with Figure 5 indicates that most of the tropopause level KE is in the zonal mean flow while in the middle and lower troposphere the KE is composed of approximately equal contributions from zonal mean and eddy flows.

The sources and sinks of energy discussed above can be summarized for the atmosphere using the 'box' diagram. Each box discussed here is a combination of zonal or eddy quantities that contribute to KE or APE. Other forms are possible, such as transient versus time mean or subdividing the eddies into different wave number groups. Arrows indicate input and output from each box as identified in the energy equations. Energy is converted back and forth between various forms, but only net changes are shown. The Hadley circulation is contained in the zonal mean quantities at the top row of the box diagram. Midlatitude frontal cyclones are included in the bottom row. The box diagram has some limitations:

1. The diagram only refers to global mean properties. For example, A_z to A_e is largest mainly in middle latitudes.
2. Only net changes are shown, whereas large regional variations occur. A_z to $K_z > 0$ for the Hadley cells but < 0 for Ferrel cells. Some studies show the global value of this conversion as negative.
3. Some conversions are simultaneous, as mentioned above, especially the A_z to A_e to K_e route by which frontal cyclones intensify. The small size of the A_z to K_z conversion hides a redundant geostrophic and hypsometric link between A_z and K_z .

Figure 13 Energy ‘box’ diagram showing reservoirs of zonal mean APE (A_Z) and KE (K_Z); eddy APE (A_E) and KE (K_E) in the same orientation as Figure 12. Also shown are net energy conversions (CA, CE, CK, CZ); and net diabatic generation or destruction. Global and annual average values indicated. The reservoirs are in units of 10^5 J m^{-2} and the conversions and diabatic processes have units of watts per square meter. The conversions are given letter labels for future reference. The numbers for A_Z and A_E are somewhat arbitrary, but consistent with each other. The values are redrawn from Marques et al. (2009) and based on ERA-40 data from 1979 to 2001. Marques, C., Rocha, A., Corte-Real, J., Castanheira, J., Ferreira, J., Melo-Gonçalves, P., 2009. Global atmospheric energetics from NCEP–Reanalysis 2 and ECMWF–ERA40 Reanalysis. *International Journal of Climatology* 29: 159–174.

4. Some conversions are hard to measure directly and are sometimes approximated (e.g., A_Z to K_Z) or deduced as a residual (e.g., G_E and A_E to K_E).
5. The box diagram gives arbitrary if not misleading results for certain situations of wave–mean flow interaction.

Observed reservoirs, conversions, sources, and sinks of energy are depicted in Figure 13. Diabatic processes create much A_Z which in turn drives K_Z of zonal mean circulations such as the Hadley cells and the zonal mean midlatitude westerlies. Some A_Z is converted into A_E which becomes K_E especially in midlatitude frontal cyclones. Convergence of eddy momentum is a net conversion of K_E to K_Z . Since friction removes K_E there must be net A_E to K_E conversion. Depending on the estimated strength of eddy frictional loss: F_E , eddy APE generation: G_E may be negative.

The box diagram for global energy shows the following:

1. While the total value of the APE is somewhat arbitrary, the relative sizes of similar energy ‘reservoirs’ are worth noting. For example, K_E is almost half of the total KE. A_E is about a tenth of the total APE.

2. The flow of energy consists primarily of G_Z to A_Z to A_E to K_E to F_E . However, the small conversion CZ can be misleading since there is some arbitrariness in how the conversions are defined as will be discussed below.
3. Different phenomena follow different paths. The A_Z to K_Z relates to the Hadley cell in terms of Figure 3. Baroclinic instability is A_Z to A_E to K_E and obviously a primary track in the diagram. Barotropic instability is K_Z to K_E and it is clearly negative (eddies feed KE into the zonal mean flow).

Transformed Eulerian Mean (TEM) and Stratospheric Energy Box Diagram

An alternative energy analysis can be constructed in a TEM framework based on an ‘eddy-induced circulation’ that results (in large part) from eddy heat fluxes. The purpose of the residual circulation is to simplify the net effect of the eddies on the mean flow in part by including their contribution to a zonal mean meridional circulation. The residual circulation (*subscripts) might be defined as

$$[v_*] = [v] - \frac{1}{p} \frac{\partial}{\partial z} \left(p \frac{[v' \theta']}{\partial [\theta]} \right) \quad [w_*] = [w] + \frac{\partial}{\partial y} \left(p \frac{[v' \theta']}{\partial [\theta]} \right) \quad [13]$$

The TEM formalism is applied more commonly to understand the stratospheric general circulation than the tropospheric. One reason is that the divergence of Eliassen–Palm flux term in the zonal momentum equation has a lot of cancelation with the flux of planetary angular momentum by the TEM residual circulation. For stratospheric planetary waves, the residual circulation induced by eddy heat flux convergence exceeds that from the diabatic heating, but that does not hold for the troposphere, in part due to the lower boundary.

If there is nonacceleration, then there is no net gain of energy in the different ‘energy boxes.’ But in some non-acceleration situations the ‘conventional’ formulation of the previous section has transfers of energy, though they are such that energy input to a ‘reservoir’ equals energy output. The transfers of energy could be viewed as misleading, since there is no net generation or destruction despite the large conversions with adjacent reservoirs. Under the same nonacceleration assumption, the energy conversions are all zero in the TEM formulation. While that might seem superior, problems arise when the nonacceleration condition is not met such as for growing baroclinic waves.

The definitions of the energy conversions differ between the TEM and conventional formulations. The TEM formulation does not allow the CA conversion, instead, energy is exchanged between waves and zonal mean through a CK conversion. However, in the TEM formulation the conversion between zonal and eddy KE is related to the Eliassen–Palm flux, which in turn is a vector that depends on eddy momentum and eddy heat fluxes.

When considering the stratosphere alone, a new source or sink of KE arises from the work done by deformation of the tropopause. These boundary fluxes are substantial and a major driver for planetary-scale stratospheric circulations. In a conventional energy cycle depiction (like Figure 13) the energy conversions would appear large, but largely go in a loop: K_Z to A_Z

to A_E to K_E and back to K_Z in the stratosphere during winter. So, much of the large conventional energy conversions do not result in corresponding large net gain or loss of energy in the individual components. The same situation in the TEM framework shows mechanical forcing of K_Z , most of which is transferred to K_E and then to A_E , where it is lost by diabatic cooling. The TEM framework is more clear than the conventional view, though it might be more physically reasonable to have a direct forcing of the stratospheric K_E by the tropospheric longest waves instead of going through K_Z first. During summer, in the stratosphere the eddies transport heat poleward making the polar region warmer than it would be from local radiative balance (geometry makes the incident solar radiation larger at the pole than at the adjacent middle latitudes), so the presence of the eddies results in polar radiative net cooling instead of net warming and the energy flow is from eddies to zonal mean.

Column Average Energetics

Vertically integrating the combination of the temperature conservation and KE equations yields

$$\begin{aligned} \frac{1}{g} \frac{\partial}{\partial t} \int_0^{P_s} (C_p T + \Phi_s + KE) dP \\ = -\frac{1}{g} \nabla_H \cdot \int_0^{P_s} (C_p T + \Phi + KE) V_H dP + Q_h + Q_f \end{aligned} \quad [14]$$

Subscript H indicates the horizontal components, KE is defined in eqn [1], and Φ_s is the surface geopotential. Q_h contains the net diabatic heating terms from the temperature conservation equation: net downward radiation at the top of the atmosphere, surface heat flux, and precipitation rate, all expressed as a heating rate. Q_f is heating due to friction (which is very small, $\sim 2 \text{ W m}^{-2}$). Vertically integrating the moisture conservation equation yields

$$\frac{L}{g} \frac{\partial}{\partial t} \int_0^{P_s} q dP = -\frac{L}{g} \nabla_H \cdot \int_0^{P_s} q V_H dP - Q_w \quad [15]$$

where Q_w is the difference in precipitation minus surface evaporation rates in the atmosphere, expressed as a heating rate. Combining the two previous equations gives an equation for a type of TE that includes internal, potential, kinetic, and latent energy:

$$\begin{aligned} \frac{1}{g} \frac{\partial}{\partial t} \int_0^{P_s} (C_p T + \Phi_s + KE + Lq) dP \\ = -\frac{1}{g} \nabla_H \cdot \int_0^{P_s} (C_p T + \Phi + KE + Lq) V_H dP + Q_h + Q_f - Q_w \end{aligned} \quad [16]$$

Hence, vertical and horizontal advections of MSE + KE are balancing the diabatic processes. A similar balance, between radiative cooling and adiabatic warming of sinking air, was exploited for the Carnot cycle model of the Hadley cell discussed above. Ignoring the tiny Q_f , eqn [14] shows that Q_h is proportional to a divergence of the flux of the combination DSE + KE. Similarly, from eqn [16] $Q_h - Q_w$ is proportional to the divergence of the TE. Hence, those fluxes can be deduced from the Q_h and $Q_h - Q_w$ fields and reveal large-scale flows of energy within the atmosphere.

Figure 14 shows the distribution of Q_h and Q_w for the extreme seasons; the total diabatic energy sources and sinks ($Q_h - Q_w$) are subdivided into quasistationary and transient contributions along with the corresponding energy fluxes. Figure 14 shows the following:

1. Q_h has strong sources in regions with heavier precipitation such as the ICZ, south Pacific convergence zone (SPCZ), and winter midlatitude frontal cyclone storm tracks. Strong surface sensible heat flux over WBCs also amplifies the Q_h .
2. Q_h is a strong sink: over winter continents due to intense radiative cooling and the eastern subtropical oceans due to negative net radiation.
3. Q_w has maxima where there is net precipitation (ICZ, SPCZ, and midlatitude winter storm tracks) and minima where there is greater net evaporation (subtropical oceans). Evaporation exceeds precipitation more strongly during winter in the subtropics. The moisture fluxes are out of the subtropics toward the ICZ, SPCZ, and midlatitude storm tracks.
4. The slowly varying diabatic sources of TE, $Q_h - Q_w$ are shown in Figure 14(c) and 14(g). The sources of TE are areas of strong evaporation over the subtropical and tropical oceans. Precipitation does not enter into eqn [16] because the flux (and hence conservation) of MSE means that latent heating is compensated by adiabatic cooling of the rising air, such as in the ICZ. Strong surface heat fluxes (and some evaporation) occur over the WBCs during winter. (During summer there is a sink over the WBCs.) During winter there is a sink of TE at higher latitudes due to the strong negative net radiation, with some enhancement of the sink over the continents.
5. The flow of TE for monthly mean and longer features is from the tropics, subtropics, and WBCs toward the higher latitudes in the vertical mean. However, for the Hadley cell, it has to be transported first equatorward, then upward, and then poleward, including phase changes of the water.
6. The faster varying diabatic sources of TE: $Q'_h - Q'_w$ (Figure 14(d) and 14(h)) are generally along the equatorial side of the midlatitude storm tracks with greater intensity during winter months. The sink tends to be immediately poleward of the storm tracks, a pattern reinforced by the TE flux.
7. The flux of TE is greatest where the $Q_h - Q_w$ gradient is greatest. The peak is in the middle latitudes ($\sim 40^\circ$ latitude) with peak value of $\sim 5 \text{ PW}$. The ocean transports heat as well, though peak values amount to $\sim 1/4$ (Northern Hemisphere) to $\sim 1/10$ (Southern Hemisphere) of the transport by the atmosphere.

Summarizing the Energy Cycle

Energy in the general circulation follows paths from sources to sinks. Energy is mathematically cast in several useful forms and it is linked to several global constraints. To provide an overview of these diverse properties, Table 1 and Figure 15 summarize how energy in kinetic and potential forms flows in the general circulation. Heat and APE are similar concepts and are compared in the table and figure. Similarly, momentum and KE may be considered together. The table and figure make clear that heat and momentum have similar circuits.

Figure 14 Vertically integrated components of the energy flow during December–February (left column) and June–August (right column) using data from 1979–2001. (a) and (e) are net diabatic heating. (b) and (f) are moisture sources and sinks (contoured) and the implied net transport (vectors). (c) and (g) are TE change (contours) and net energy fluxes (vectors) due to ‘quasistationary’ processes varying on monthly mean or longer timescales. (d) and (h) are similar to (c) and (g) but for ‘transient’ processes varying faster than monthly mean timescales. The sources and sinks are all expressed as energy fluxes with units of watts per square meter. The vector scales and units are indicated with a reference vector in the lower right corner of individual panels. Reproduced from Trenberth, K., Stepaniak, D., 2004, The flow of energy through the earth’s climate system. *Quarterly Journal of the Royal Meteorological Society*, 130: 2677–2701.

Table 1 Stages in the APE (heat) and KE (momentum) energy cycle

APE or heat flow	KE or momentum flow
1. Solar and terrestrial radiation create excess heating in the tropics and a deficit poleward of 38°. 2. Result of item (1) is a poleward heat flux. 3. In midlatitudes eddies are the main mechanism for heat transport. 4. The CA and CE conversions (see Figure 13) show that horizontal and vertical heat fluxes create eddy energy (baroclinic process). Latent heat release may also contribute. 5. Net radiation being positive causes the heat flux to increase with latitude in the subtropics. (More and more heat must be transported poleward to maintain quasisteady PE.) 6. The eddy heat flux is down the T gradient. 7. The heat flux is maximum where net radiation is zero. 8. Poleward of the heat flux maximum there is cooling by net radiation.	1. Westerly momentum is introduced in the tropics and is removed by friction in midlatitudes. 2. Result of item (1) is a poleward westerly momentum flux. 3. In midlatitudes eddies are the main mechanism for momentum transport. 4. Eddy momentum fluxes also provide sources and sinks of eddy KE from the CK conversion (see Figure 13). Since global average CK is positive, eddies must lose KE to the mean flow in the net (barotropic process). 5. The flux of zonal mean KE keeps increasing with latitude in the subtropics where CK is positive. (More and more momentum must be transported poleward to maintain quasisteady KE.) 6. Eddy momentum flux is up the gradient of $[u]\cos^{-1}\phi$ at many latitudes. 7. The flux of (KE) reaches a maximum where CK equals zero. 8. Poleward of the angular velocity, $[u]\cos^{-1}\phi$, maximum, eddies remove energy from (KE) in the net.

Figure 15 (a) Schematic meridional cross sections of the atmospheric cycles of (a) APE and heat and (b) KE and momentum. Arrow lengths are intended to suggest relative magnitudes. In panel (a) single-shafted arrows depict radiation (straight for absorbed solar; wavy for terrestrial emitted to space) with representative numerical values given in watts per square meter. Double-shafted arrows depict heat fluxes (dashed for latent; wavy for sensible heat). Letters correspond to distinct parts of the cycle. Solar radiation (a) is absorbed in the tropics and subtropics, then that heat energy is transported (b) equatorward. Latent heat (c) is converted into sensible heat in the ICZ then transported poleward (d) in the upper troposphere. Sinking in the Hadley cell (e) brings heat downward. Eddy fluxes (f) extract heat from the subtropics and are augmented by surface fluxes (g) at WBCs. Heat is mixed upward vertically (h) in frontal cyclones, whereupon a net loss occurs to space (i). A weak poleward flux (k) results from the eddy-induced stratospheric circulation. In panel (b), momentum transport in the troposphere is separated into mean meridional cells (solid arrows) and eddies (dashed arrows). Letters correspond to these parts of the cycle: Slowing down surface easterlies imparts westerly momentum (a) into the tropical boundary layer. That momentum is transported equatorward (b) then upward (c) in the ICZ convection. The upper Hadley cell transports the momentum (d) poleward. Eddies further transport the momentum (e) poleward, out of the subtropics, while the Ferrel cell (f) both opposes the eddy flux and mixes some momentum downward. Frontal cyclones also have a net downward mixing (g) of westerly momentum (e.g., behind cold fronts) that is lost by friction at the surface (h). The transport creates westerly momentum convergence in the subtropics and midlatitudes forming a subtropical jet (J) and a KE maximum there, (k) and other arrows in the stratosphere are meant to indicate mechanical forcing by the midlatitude ultralong waves and by deep tropical convection.

Westerly momentum is defined positive, so frictional slowing of easterlies in the tropical boundary layer is a *source* of westerly momentum but a *sink* of KE. The low-level flow in the Hadley cells gains westerly momentum and transports it equatorward. Surface fluxes of heat and water provide a diabatic source of warmth and moisture to air parcels as they approach the ICZ.

In the ICZ, westerly momentum is transported to the upper troposphere. Latent heat is released where the efficiency factor is large and positive, leading to strong diabatic generation of APE. While the precipitation does not contribute directly to the TE generation, it does reinforce the equatorward pressure gradient that drives the upper level Hadley cell motion, establishes the westerlies, and creates other indirect impacts.

The upper branch of each Hadley cell transports westerly momentum poleward. Conservation of angular momentum builds the velocity relative to the Earth's surface, i.e., creating KE and providing one mechanism to create the subtropical jets. The poleward extent of the motion arises from interaction between the (poleward) pressure gradient force and the Coriolis force (at a right angle to the motion); these two forces would accelerate parcels along a trochoidal path. Because the MSE of the poleward moving air is much greater than the MSE of the equatorward moving air below, the Hadley cell has a net poleward transport of heat.

The subtropical oceans are where much energy is input into the atmosphere through evaporation. The subtropics are also a transition between the convection-dominated tropical circulations and the frontal cyclone-dominated midlatitude circulations. Negative net radiation encourages parcels in the Hadley cell to sink, bringing down some westerly momentum as well as high potential temperatures. The frontal cyclones mix momentum and heat vertically. The vertical fluxes of heat by each cyclone and the vertical shear of the jet streams both are fundamental parts of the baroclinic instability mechanism.

In middle latitudes, air in the cyclones' warm sector has a poleward component of motion, while air in the cold sector moves equatorward: in both sectors *eddy* heat transport is poleward. Much precipitation accompanies the frontal cyclones with the bulk of it occurring in the warm sector, so there may be diabatic generation of eddy APE but loss of zonal APE. Further poleward, radiative cooling, especially from cloud tops, generates APE. Mature frontal cyclones develop momentum fluxes that converge upper level westerly momentum, while their heat fluxes reduce the meridional temperature gradient on a zonal average. To maintain thermal wind balance a secondary circulation forms which also transports momentum (equatorward at upper levels). The westerly momentum mixed to the surface (for example, in subsiding air of cold sectors) is removed by friction in the boundary layer, becoming a sink of westerly momentum and of KE.

In the stratosphere, there is input of mechanical (kinetic) energy by tropical convection and by midlatitude long waves as well as heating as ozone absorbs radiation. The eddy-induced circulation transports some heat poleward though angular momentum is mixed vertically and horizontally.

Introduction

The atmosphere can be regarded as a dynamical system with an infinite number of degrees of freedom. If one considers the whole spectrum of atmospheric phenomena, covering different spatial and temporal scales, the number of states that can be assumed by the atmospheric variables is indeed infinitely large. However, when interest is restricted to the large-scale features of the atmospheric circulation (especially in the extratropics during the cold season), many statistical analyses of the multidecadal record of observed data suggest the existence of preferred circulation patterns that seem to be particularly recurrent and/or persistent.

Examples of these recurrent flow types are presented in **Figure 1**: the monthly mean geopotential height at 500 hPa in January of four different years is shown, superimposed on the corresponding anomalies (i.e., deviations from climatology) over the northern extratropical regions. It is evident that the two circulation anomalies shown in each row of **Figure 1** are quite similar to each other, while there are strong differences between the anomalies in the top row and those in the bottom row. Indeed, these two sets of patterns are characterized by nearly opposite anomalies over the north-east Pacific and most parts of North America and Eurasia.

Several explanations have been proposed for the existence of preferred circulation patterns. Some of them are based on

Figure 1 Monthly mean geopotential height at 500 hPa (black solid contours) and its deviation from the climatological mean (shaded) in (a) January 1981, (b) January 1986, (c) January 1982, and (d) January 1991. Contour interval 100 m for full fields, 60 m for anomalies.

linear theories of the interactions between the observed time-mean state of the atmosphere and large-scale circulation anomalies. Because of the zonal asymmetry of the climatological basic state, some large-scale patterns may be much more efficient than others in amplifying at the expense of the energy of the time-mean state, or may generate a much stronger response to anomalies in the distribution of diabatic heating.

Theories of a different kind are based on the nonlinear nature of the equations that govern the atmospheric motion. Because of their nonlinearity, these equations may possess a number of different stationary states. The so-called multiple equilibria of a number of highly simplified atmospheric models have therefore been proposed as an explanation of the preferred persistent anomalies of the atmospheric circulation.

In reality, no observed atmospheric state is exactly stationary: even though large-scale features may remain relatively constant, unstable synoptic disturbances always generate variability of the day-to-day weather. On the other hand, the intensity and geographical distribution of the weather events is strongly affected by the characteristics of the large-scale flow. Therefore, rather than looking at the equilibria of the instantaneous flow, it may be more appropriate to investigate the quasi-stationary states produced by the interactions of large-scale flow anomalies with the associated distribution of synoptic-scale disturbances. These statistical-dynamical equilibria, which involve interactions between phenomena with different spatial and temporal scales, are usually referred to as 'weather regimes' or 'flow regimes'.

The concept of multiple equilibria has been used to explain nonlinear phenomena in many branches of physical climatology and geophysical fluid dynamics. In oceanography, for example, it is widely accepted as an explanation of some aspects of the long-term variability of the thermohaline circulation. In atmospheric sciences, theories of multiple equilibria have always been more controversial, partly because of the highly simplified nature of the models proposed, partly because of the difficulty of finding observational evidence to support them. The concept of weather regimes, on the other hand, has been more widely accepted, since such regimes have been simulated in a number of intermediate-complexity models that produce a fairly realistic description of the atmospheric flow.

The summary of theoretical and observational studies on flow regimes given in the following sections will be focused on the northern extratropical circulation, following the majority of investigations on this issue. It should be mentioned that the existence of weather regimes in the Southern Hemisphere and in the tropical circulation has also been advocated. Whether a regimelike behavior may explain some aspects of the variability of the Asian summer monsoon is currently a much-debated issue. On the basis of results from simplified numerical models of the monsoon circulation, it has been suggested that the interannual variability arising from anomalies in tropical sea surface temperatures may be represented (particularly in the Indian region) by a modification of the frequency of two regimes corresponding to the so-called active phases and break phases of the monsoon. So far, the observational evidence supporting this interpretation of monsoon variability is scarce. However, the relationship between the statistical properties of regimes and variations in atmospheric forcing is

receiving attention also for the extratropical regions, since it may be a key to understanding the regional patterns of atmospheric response to the perturbations of the Earth's radiative balance arising from anthropogenic emissions of greenhouse gases.

Dynamical Models with Multiple Equilibria and Flow Regimes

The first (and simplest) atmospheric model that has been used to investigate the existence of multiple equilibria is represented by the barotropic vorticity equation forced by bottom topography. If ψ is the streamfunction at the equivalent barotropic level, and $\mathbf{V}_\psi$ given by eqn [1] is the associated nondivergent wind, the model can be written as eqn [2].

$$\mathbf{V}_\psi = \left(-\frac{\partial\psi}{\partial y}, \frac{\partial\psi}{\partial x} \right) \quad [1]$$

$$\begin{aligned} \frac{\partial \nabla^2 \psi}{\partial t} + \mathbf{V}_\psi \cdot \nabla \left[\nabla^2 \psi + f \left(1 + \frac{H}{H_0} \right) \right] \\ = -k \nabla^2 (\psi - \psi^*) \end{aligned} \quad [2]$$

where f is the Coriolis parameter, H/H_0 is the topographic height scaled by a suitable reference value, k is a dissipation coefficient, and ψ^* is an equilibrium state in the absence of topography.

A minimal version of this model (either in a so-called beta-channel or in a hemispheric domain) can be obtained by expressing ψ as a linear combination of just three orthogonal functions as in eqn [3].

$$\psi = u\Psi_0(y) + w_1\Psi_1(x, y) + w_2\Psi_2(x, y) \quad [3]$$

In eqn [3], Ψ_0 represents the zonal-mean flow; Ψ_1 and Ψ_2 represent the two components (in quadrature along the x -direction) of a planetary-scale Rossby wave that has near-zero phase speed when the zonal mean flow is close to its time-mean value. If the three functions Ψ_0 , Ψ_1 , and Ψ_2 are normalized in such a way as to have the same kinetic energy, the flow is relaxed toward a zonal-mean state $\psi^* = u^*\Psi_0$, and the topographic height is assumed to project only on Ψ_1 , then the model represented by eqn [2] is reduced (by a suitable scaling) to the three-variable dynamical system [4] and [6].

$$\dot{u} = -hw_2 - k(u - u^*) \quad [4]$$

$$\dot{w}_1 = (u - u_0)w_2 - kw_1 \quad [5]$$

$$\dot{w}_2 = -(u - u_0)w_1 + hu - kw_2 \quad [6]$$

In these equations, u_0 represents the value of u at which the planetary wave (Ψ_1, Ψ_2) is stationary, and h is a coefficient proportional to the topographic height. The nonlinear terms in eqns [5] and [6] arise from the absolute vorticity advection, while the terms proportional to h in eqn [4] and [6] represent the orographic drag on the zonal-mean flow and the orographic forcing of planetary waves, respectively.

For a given value of h , the system [4] and [6] possesses only one (stable) stationary solution when u^* is sufficiently small. Above a bifurcation value for u^* , three stationary solutions exist, one of which is unstable. Of the two stable equilibria, that

with the stronger zonal wind has a planetary wave pattern with a ridge approximately centered over the orographic maxima (i.e., $u > u_0$ and $w_1 > 0$). In the second stable state (with $u < u_0$ and $w_1 < 0$) the planetary wave pattern has a stronger amplitude, and is out of phase with respect to the topography. Examples of these stationary solutions are illustrated in Figure 2; the equilibrium with larger wave amplitude was originally interpreted as the counterpart of the atmospheric regimes characterized by blocking highs over the eastern sides of the oceans.

Because of the existence of stable steady states, the simple barotropic model above cannot simulate transitions from one regime to another. Trajectories started in different parts of the model phase-space will converge to either of the two ‘fixed points’ represented by the stable steady states. In the real extratropical flow, transitions from one regime to the other are due to a combination of barotropic and baroclinic instability, which can only be reproduced by multilevel models with wave components of different wavenumber.

A number of diagnostic studies, however, have revealed that high-frequency transients do not simply act as quasi-stochastic perturbations causing transitions between regimes. Instead, they interact with the large-scale flow in such a way as to modify the dynamical equilibria of the system. For example, in the case of blocking highs, it has been shown that the nonlinear feedback of transient eddies onto the large-scale anomaly tends to counterbalance the dissipative processes in the lower troposphere, and to oppose the downstream advection of the blocking pattern by the zonal-mean flow in the upper troposphere.

These processes may be simulated by a multilevel quasi-geostrophic model, described (at individual pressure levels) by an equation of the form [7].

$$\frac{\partial q}{\partial t} + \mathbf{V}_\psi \cdot \nabla q = -\mathbf{D}(\psi - \psi^*) \quad [7]$$

In eqn [7], q is the quasi-geostrophic potential vorticity (PV) given by eqn [8].

$$q = \nabla^2 \psi + f + f_0^2 \frac{\partial}{\partial p} \left(\frac{1}{\sigma} \frac{\partial \psi}{\partial p} \right) \quad [8]$$

σ is the appropriate static stability parameter, and $\mathbf{D}$ is a linear, multilevel operator representing dissipative processes that relax the model streamfunction toward ψ^* . A forcing term for planetary waves can be introduced in this model either by defining a zonally asymmetric ψ^* (for example, to simulate the thermal contrast between oceanic and continental regions during the Northern Hemisphere winter) or by introducing orographic forcing through an additional term in the definition of PV at the lowest model level (analogous to the orographic term in eqn [2]).

To introduce the concept of weather regimes, it is convenient to decompose the streamfunction field into a low-frequency component and a high-frequency component by introducing a time scale τ , equal to a typical lifetime of persistent large-scale anomalies. For the extratropical flow, τ is of the order of 10 days. If the overbar represents a (running) mean over time τ , the low-frequency component can be defined as $\bar{\psi}$, and the high-frequency part as $\psi' = \psi - \bar{\psi}$.

The time-averaged version of eqn [7] is given in eqn [9], where the last term on the right-hand side represents the nonlinear feedback of the high-frequency transients onto the low-frequency component.

$$\frac{\partial \bar{q}}{\partial t} + \bar{\mathbf{V}}_\psi \cdot \nabla \bar{q} = -\mathbf{D}(\bar{\psi} - \psi^*) - \overline{\mathbf{V}_{\psi'} \cdot \nabla q'} \quad [9]$$

This quantity should be regarded as a statistical–dynamical variable; its expected value (for any given $\bar{\psi}$) will be indicated as in eqn [10].

$$F'(\bar{\psi}) = -\langle \mathbf{V}_{\psi'} \cdot \nabla q' \rangle \quad [10]$$

Figure 2 Streamfunction (thick solid contours) of the two stable stationary states of eqns [4] and [6], with $u_0 = 10$, $u^* = 12$, $h = 0.3$, $k = 0.6$. (a) State with $u > u_0$, (b) state with $u < u_0$. The topographic height is shown in thin contours (solid for positive values, dashed for negative values). Units are arbitrary.

Weather regimes can be defined as the solution of the statistical-dynamical equation [11].

$$\bar{\nabla}\psi \cdot \nabla \bar{q} = -D(\bar{\psi} - \psi^*) + F'(\bar{\psi}) \quad [11]$$

That is the weather regimes are those low-frequency patterns for which a balance between large-scale PV advection, dissipation, and feedback from high-frequency transients is achieved. As mentioned above, the high-frequency term is mainly balanced by large-scale advection in the upper troposphere and by dissipation in the lower troposphere.

Except for very idealized models, it is very difficult to write an analytical formulation of the term F' as a function of $\bar{\psi}$. Therefore, in studies performed with intermediate-complexity models, a semiempirical approach has often been used, in which first a very long integration of the original model equations is performed, then individual realizations of the high-frequency feedback are computed (each one corresponding to a $\bar{\psi}$ field in the model-generated time-series), and finally F' is defined as a weighted average over a neighborhood of $\bar{\psi}$ in a suitable subspace of the model phase-space. This methodology can also be adapted to the diagnostic analysis of observed data.

Another approach, applicable to the analysis of both modeled and observed data, is based on the search for multiple maxima (i.e., modes) in the probability density function (PDF) of the variables describing the low-frequency flow. If flow regimes do correspond to quasi-stationary states, then the large-scale flow patterns corresponding to them should be more persistent than other patterns, and this should be reflected in a higher probability density in phase-space.

An example of regimes of a three-level quasi-geostrophic model, identified by multiple maxima in the PDF of large-scale parameters, is given in Figure 3 and Figure 4. The model used for this integration has about 500 degrees of freedom for each level, covers a global domain, and represents the planetary wave forcing due to (real) topography and to vorticity sources generated by tropical convection. In models of this kind, it is difficult to select a priori the variables that are expected to display a multimodal behavior. Therefore, multivariate statistical analysis of the modeled variability is often used as a preliminary step to identify the most relevant parameters. Figure 3 shows the bidimensional PDF of the first two principal components (PCs) of streamfunction anomalies at 500 hPa, computed from 5-day means over the Pacific–North American region. The spatial patterns associated with these PCs (called empirical orthogonal functions, EOFs) are shown in Figure 4(a) and 4(b) and represent planetary wave anomalies with maximum amplitude in the north-eastern Pacific and over the western coast of North America. The PDF is bimodal, with one maximum along the PC-1 axis, and a second one along the PC-2 axis. Therefore, the two EOFs shown in Figure 4 and Figure 4 are also representative (in this particular case) of the anomalies associated with the two regimes of the model. In Figure 4 and Figure 4, the full 500 hPa streamfunctions corresponding to these regimes are shown. In the first regime, a predominantly zonal flow covers most of the North Pacific, and a ridge of moderate amplitude is centered on the western edge of the North American continent. In the second regime, the ridge has a stronger amplitude, its axis is shifted about 30° upstream, and an anticyclonic circulation prevails over the north-east Pacific.

Figure 3 Probability density function (PDF) in the plane spanned by the first two principal components of 500 hPa streamfunction in the Pacific–North American region, from an integration of a three-level quasi-geostrophic model representing topographic forcing and tropical vorticity sources (PC-1, x-axis; PC-2, y-axis). Adapted from Molteni F and Corti S (1998) Long-term fluctuations of the statistical properties of low-frequency variability: Dynamical origin and predictability. Quarterly Journal of the Royal Meteorological Society 124: 495–526.

Are these regimes the counterparts of the multiple equilibria of highly truncated barotropic or baroclinic models, such as the three-variable system described by eqns [4] and [6]? The answer is not straightforward. Even when one considers the minimal two-level model in which interactions between planetary waves and baroclinically unstable synoptic-scale waves are represented, one does not find a one-to-one correspondence between stationary solutions and regimes. There are different reasons for this. First, in models with chaotic attractors, quasi-stationary regimes (if any) may only occur in the neighborhood of weakly unstable steady states, while no regimes are associated with strongly unstable equilibria. Second, baroclinically unstable eddies grow at the expense of the available potential energy (APE) of the time-mean flow, and therefore the mean effect of the term F' in eqn [11] is equivalent to a sink of APE. Since a reduced energy source will be available for direct energy conversions from the time-mean flow to large-scale anomalies, the planetary waves associated with flow regimes may have a smaller amplitude than those corresponding to the stationary states of the instantaneous flow for the same forcing parameters.

On the other hand, the flow-dependent component of F' may act as a kinetic energy source for the large-scale anomalies, maintaining them against dissipation. This is especially the case for dipolar structures resembling atmospheric blocking patterns. In fact, multiple regimes associated with the alternation of blocked and zonal flows, occurring downstream of a region with enhanced westerlies, have been simulated in quasi-geostrophic models possessing only one stationary solution for the instantaneous flow.

Figure 4 Empirical orthogonal functions (EOFs) (a, b) of 500 hPa streamfunction in the Pacific–North American region, and streamfunction patterns (c, d) corresponding to the two regimes (PDF maxima) in Figure 3, from an integration of a three-level quasi-geostrophic model representing topographic forcing and tropical vorticity sources. (a) EOF-1; (b) EOF-2; (c) streamfunction for regime with positive PC-1; (d) streamfunction for regime with positive PC-2. Units: $10^6 \text{ m}^2 \text{ s}^{-1}$. Regimes in the Extratropical Atmosphere

A number of dynamical models of the atmospheric circulation that possess multiple steady states and/or regimes have been described in the scientific literature. At least for the extratropical flow in the Northern Hemisphere winter, a reasonably good understanding of the dynamical mechanisms that lead to the formation of flow regimes has been established. However, finding observational evidence of regime-like behavior in the real atmosphere has been a much more difficult task, often leading to controversial results.

In the early 1980s, attempts to detect a ‘signature’ of flow regimes in the atmospheric flow were guided by the results of theoretical studies on topographically forced multiple equilibria. Emphasis was therefore put on the analysis of indices of the intensity of zonal wind and of planetary wave amplitude in northern mid-latitudes. Although no evidence of multiple regimes was obtained from the analysis of zonal-mean wind (as justified by later theoretical and modeling studies), an index of the combined amplitude of planetary waves with zonal wavenumbers 2 to 4 showed a bimodal behavior when computed from a multiyear record of analyses of 500 hPa geopotential height. These findings, extended from a few years to about four decades of data in subsequent analyses, have been subject to a lot of critical scrutiny because of the sensitivity of the detected bimodality to the specific definition of the planetary wave index (namely, to the extent of the latitudinal band in which waves are analyzed and to the time-filtering procedure applied to the time series). Despite these uncertainties, the discovery of bimodality in the planetary wave index was quite a fundamental step in advancing the nonlinear theories of flow regimes to the role of reputable candidates for the explanation of extratropical low-frequency variability.

Part of the problems affecting the significance of the planetary wave index were related to the difficulty of condensing all information about the regime structure into a single index, defined a priori on the basis of theoretical considerations. Alternative approaches to the analysis of large-scale flow patterns were attempted in which multivariate statistical techniques were used to identify a suitable low-dimensional space in which the search for regimes could be performed effectively. The simplest of these approaches consisted in performing a PC analysis of observed planetary wave fields, and looking for bimodality in the combined amplitude of the leading PCs. In later studies, the leading PCs of anomalies of 500 hPa height were used to search for local maxima in multidimensional PDFs, or as input to cluster analysis techniques. In all cases, the goal was to reveal the ‘coarse grain’ structure of the attractor for the extratropical low-frequency circulation.

If on the one hand the search of regimes in multidimensional spaces removed some of the constraints associated with the definition of a unidimensional index, on the other it introduced greater difficulties in assessing the statistical significance of the results. Also, the arbitrariness in the choice of the domain is still present in multidimensional analyses. While some studies were concerned with regimes of the whole extratropical circulation (either in the Northern or in the Southern Hemisphere), it was argued that separate analyses of the regimes in the North Atlantic and North Pacific regions would provide more meaningful results because of the regional nature of the interactions between large-scale anomalies and high-frequency transients in the Atlantic and Pacific stormtracks.

Differences in methodologies, space–time domains, and dimensionality of the analyzed subspaces have produced regime classifications that obviously are not entirely compatible with one another. Still, consistency can be found in at least a subset of the regimes identified by different research groups.

From the analyses of the whole northern extratropical flow, a widespread consensus is found on the existence of two regimes that are well represented by the flow patterns in the top row and the bottom row, respectively, of Figure 1. When related to the results of linear teleconnection studies, these two regimes are characterized by opposite phases of the Pacific–North American teleconnection pattern. A third regime found in most Northern Hemisphere studies, and in analyses focused on the Atlantic sector, is associated with the negative phase of the North Atlantic Oscillation pattern and a general reduction in the strength of high-latitude westerlies. More examples of regimes defined in the Euro-Atlantic region will be given below.

Interannual and Interdecadal Variability of Regimes

One fundamental difficulty arising in the interpretation of observational analyses of flow regimes is due to the non-stationarity of the energy sources for the atmospheric flow. In theoretical and simplified numerical models of the large-scale flow, the statistical properties of the circulation depend on the amplitude and spatial distribution of the forcing terms acting as energy sources for the model. Usually, multiple regimes occur only in a certain range of the forcing parameters

and, within that range, regime properties such as the position in phase space and the frequency of occurrence depend on the parameter values.

In the real atmosphere, apart from the periodic fluctuations due to the seasonal cycle, the energy sources for the atmospheric flow are modified by interannual and interdecadal variations in the properties of the surface boundary (e.g., sea surface temperature, snow, and sea ice distribution) arising from the long-term natural variability of the whole climate system. In addition, the planetary radiative balance is being altered, in a slow but continuous way, by the changes in the concentration of radiatively active constituents produced by human activities. Therefore, even when the yearly cycle is accounted for by computing anomalies with respect to a seasonally varying climate, the multidecadal sample of observed anomalies in any given season is not homogeneous as far as the forcing terms are concerned.

The effect of these forcing variations on the regime properties are very difficult to distinguish from the natural fluctuations due to the chaotic nature of the atmospheric dynamics. Based on the theoretical behavior of nonlinear dynamical systems, one may hypothesize two different kinds of response. In one scenario, multiple regimes are well defined and the forcing variations are small compared to the range of forcing

Figure 5 Probability density function (PDF) in the plane spanned by the first two principal components of wintertime (Dec–Mar) monthly mean 500 hPa geopotential height in the Euro-Atlantic region, computed from the reanalyses of the US National Centers for Environmental Prediction. (a) Data from 50 winters, 1948/49 to 1997/98; (b) data from 25 winters, 1948/49 to 1972/73; (c) data from 25 winters, 1973/74 to 1997/98.

parameters in which those regime exist. In this case, the circulation patterns associated to the regimes will not be strongly modified, but the stability of the regimes may be altered in such a way that the frequency of occurrence of one (or more) regimes will be increased, while other regimes will become less populated. Alternatively, if the system is close to a bifurcation point, or the forcing terms are changed substantially, then the patterns or even the number of regimes may be modified.

Which scenario is better suited to describe the observed atmospheric behavior? The answer may depend on the region considered. [Figure 5](#) shows the bidimensional PDF of the first two principal components of wintertime monthly mean anomalies of 500 hPa geopotential height in the Euro-Atlantic sector of the Northern Hemisphere (20° – 90° N, 90° W– 60° E). The first PC, corresponding to the x -axis in the figure, is an index of the North Atlantic Oscillation (NAO). [Figure 5\(a\)](#)

shows the PDF for the whole 50-winter record available, while [Figure 5\(b\)](#) and (c) show the PDF computed from the first half and the second half of the record, respectively.

The 50-winter PDF has three well-defined modes (i.e., local maxima), which are associated with the anomalies shown in [Figure 6](#). The regime corresponding to positive PC-2 (y -axis) shows a positive anomaly covering the central part of the North Atlantic, corresponding to an enhanced planetary wave ridge in this region. The other two modes, which occur at small negative values of PC-2, represent opposite phases of the NAO. In the negative phase, an anticyclonic anomaly develops over Greenland, which strongly reduces the westerly flow in the Atlantic poleward of 50° N. In the positive phase, the high-latitude westerlies are strengthened, and an anticyclonic anomaly develops over central Europe. These regimes have been found in a number of observational studies of Atlantic

Figure 6 Anomalies of 500 hPa geopotential height (m) corresponding to the three regimes (PDF maxima) in [Figure 5](#). (a) Regime with positive PC-1 and positive PC-2 (Atlantic ridge); (b) regime with negative PC-1 and negative PC-2 (Greenland anticyclone); (c) regime with positive PC-1 and negative PC-2 (zonal flow with positive NAO phase).

variability (although more detailed analyses reveal at least one more regime, associated with a blocking high over Europe) and also correspond quite well to the Euro-Atlantic portion of the most reproducible hemispheric regimes.

If one looks at the PDFs for the two halves of the records, the first two modes may be clearly identified in both periods, although with different amplitude. Conversely, the mode corresponding to positive NAO is only evident in the second half of the record. This behavior is consistent with a widely documented trend of the NAO index in the last few decades. This trend is not simply reflected in a uniform shift of the PDF in the PC plane: although a partial shift is detectable, the most relevant effect is the appearance of the third mode corresponding to positive NAO. Overall, the regime change in the Atlantic region seems to fall into an intermediate category between the two theoretical scenarios outlined above.

One of the main differences between the properties of low-frequency variability in the Atlantic and Pacific sectors arises from the different importance of tropical–extratropical interactions in the two regions. While the interannual variability associated with tropical sea surface temperature anomalies accounts for a small fraction of the total variability in the Atlantic, the extratropical Pacific is strongly influenced by the El Niño Southern Oscillation (ENSO) phenomenon. Since the east–west asymmetry in the distribution of diabatic heating in the tropical Pacific is an important source of forcing for the planetary waves in the region, the changes in convective activity induced by ENSO cannot be regarded as weak anomalies in the forcing patterns. A number of observational and modeling studies have found that the intensity of low-frequency variability in the North Pacific region is enhanced in the cold ENSO phase (La Niña) and reduced during warm (El Niño) events. In fact, there is little evidence of multiple regimes in the Pacific during strong El Niño events.

Synopsis

The large-scale average conditions of the atmosphere are described. Emphasis is placed on the primary observed variables: radiation, temperature, pressure, wind, clouds, and precipitation rate. Zonal and time average fields as well as time average fields at representative levels are shown.

Introduction

The atmosphere of the Earth has a diverse range of motions. The general circulation refers to the larger scale motions having horizontal length scales greater than 1000 km and persisting for a season or longer. In addition, this subject includes all processes necessary to explain sufficiently, or maintain directly, the large-scale circulation.

The general circulation is a broader subject than simply the large-scale movement of air. Understanding the circulation requires examination of other atmospheric quantities. The large-scale circulations are created by imbalances in the radiation fields that lead to temperature gradients that the atmosphere tries to eliminate. The circulations that develop are limited by various physical constraints such as radiative energy balance, mass balance, and angular momentum balance. So, while the primary scope of this article is to display the average properties of circulation, it is also necessary to consider related variables that are directly observed. The related variables are connected by constraints and the underlying laws of dynamics and thermodynamics. Other articles on the general circulation discuss how the circulation is maintained and how it can be simulated.

The general circulation of the atmosphere has complex structure in all dimensions as it evolves over the seasons. However, the Earth rotates fast enough relative to the radiative response time of much of the atmosphere so that many properties of the atmosphere have a strong zonal average component. To make a discussion of this subject manageable, the properties of a variable are first shown when longitudinal averages are taken in addition to seasonal time averages. Longitude averages are commonly labeled 'zonal means'. Zonal averages do miss important phenomena that can be seen in time averages. Time means reveal longitudinal variations that one must consider in order to understand the properties as well as the maintenance of the zonal mean state. The three-dimensional structure of time averages is illustrated by showing horizontal maps of time-averaged fields at a few representative levels.

The general circulation undergoes seasonal change. In many fields, the seasonal change is much less in the Southern Hemisphere than in the Northern Hemisphere. The difference arises because the middle latitudes in the Southern Hemisphere have a much higher fraction of ocean coverage than in the Northern Hemisphere. Land and ocean have different thermodynamic properties: heating and cooling are more readily mixed through a greater amount of mass in the ocean than on the land; the albedo of land can change drastically with season unlike ice-free ocean, and water has a higher heat capacity

than soil. These factors magnify seasonal change over large landmasses.

The difference in middle latitude land coverage has another implication. There are more major mountain ranges in the Northern Hemisphere. The mountains, along with differences that arise between land and sea areas, lead to more prominent planetary waves in the Northern Hemisphere. Alternatively, many fields in the Southern Hemisphere tend to be more zonally uniform.

Radiation and Temperature

Radiation

A discussion of the general circulation starts with radiation, since the distribution of radiation absorbed and emitted is the ultimate driving mechanism for the circulation.

The Earth (including its atmosphere, solid, and ocean parts) absorbs radiation emitted by the Sun. While the Earth rotates about an axis that is tilted with respect to the Sun, the equator is perpendicular to the Sun's rays on an annual average. Simple geometry (see [Figure 1](#)) shows that the solar radiation reaching a unit horizontal area on the Earth diminishes from equator to pole. The amount of solar radiation absorbed is influenced by the reflectivity of the Earth's surface, the amount of cloud cover, and the path length through the atmosphere. On an annual average, the amount of radiation absorbed decreases greatly from the equator toward each pole ([Figure 1](#)). The rate that absorption decreases with latitude is greater in polar than in tropical regions.

To balance the radiant energy absorbed, the Earth emits energy back to space. Like the absorbed solar radiation, terrestrial emission also decreases from the equator toward each pole on an annual average. The terrestrial emission is governed by the temperature and the radiative properties of the emitter. Emission comes from the surface of the Earth as well as from the atmosphere. For equivalent radiative substances, more radiant energy is emitted from objects having higher temperature. So, the terrestrial emission shown in [Figure 1](#) is consistent with the tropics being warmer than the polar regions. A key fact is that the emission does not change with latitude nearly as fast as does the absorption. Consequently, most latitudes are not in radiative equilibrium and there is a net radiation surplus in the tropics (more solar radiant energy is absorbed than terrestrial radiation is emitted). At latitudes higher than 38°, there is a net radiation deficit (more emission than absorption locally). In order to sustain the surplus and deficit over time, a poleward energy transport is required, and that has implications for the temperature field. The terrestrial

Figure 1 Schematic diagram of solar radiation reaching two horizontal areas on the Earth at an equinox. Inset: annual average latitudinal distribution of incoming solar (dotted line), absorbed solar (short dashed line), and terrestrial emission (solid line) in watts per square meter. A stretched latitude is used based on the area within each latitude band. Data from National Center for Environmental Prediction (NCEP)/Department of Energy (DOE) AMIP Reanalysis II four times daily mean data averaged from January 1979 through December 2009.

emission means that temperatures are lower in the tropics and warmer in the polar regions than they would be if there was no heat transport. While some transport occurs by the oceans, the remainder occurs in the atmosphere and to transport thermal energy the atmosphere must have circulation. The atmosphere may transport the heat by direct means (labeled sensible heat transport) or by transporting water vapor (labeled latent heat transport). The latter process gains or releases heat during a phase change of the water. So, the distribution of radiation implies links to temperature, velocity, and moisture fields.

The solar absorption and terrestrial emission shown in **Figure 1** are plotted on a stretched latitudinal scale. The stretching is proportional to the horizontal area of each latitude band. Consequently, the annual average energy balance for the Earth as a whole is also seen in the figure because the area under the dashed line equals the area under the solid line. More is said about the energy distribution and flow elsewhere in the encyclopedia (see **General Circulation of the Atmosphere: Energy Cycle**).

While **Figure 1** shows the zonal average distribution of absorbed and emitted radiations, the longitudinal distribution of these two quantities is shown in **Figure 2**. The annual

Figure 2 Annual radiative balance for the Earth. (a) Time average incoming, downward, solar, and absorbed radiation estimated at the top of the atmosphere. (b) Time average upwelling, longwave radiation from the Earth. (c) Net radiation, the solar minus terrestrial radiation difference. NCEP/DOE AMIP Reanalysis II four times daily mean data averaged from January 1979 through December 2009. Contour interval is 20 W m^{-2} .

average solar radiation absorbed (**Figure 2(a)**) has a strong zonal mean component over the oceans. The principal deviations from the zonal average are over ice-covered regions (Greenland) and desert areas (Sahara and Arabia). Both areas have high annual average reflectance due to a bright surface. Variation across each ocean basin occurs with greater cloudiness along the storm tracks (discussed below) such that those tracks avoid the eastern sides and allow more solar absorption on the east side. The dips in the zonal average radiant energies near 10° N latitude (**Figure 1**) are a consequence of persistent high-elevation cloudiness associated with the intertropical convergence zone (ICZ). The ICZ is seen in **Figure 2(a)** as most of the lower values in the tropics that occur over the

major landmasses and along a narrower band across the oceans. The annual average terrestrial radiant flux at the top of the atmosphere (**Figure 2(b)**) also has a strong zonal mean component over oceans. Longitudinal variations occur over the eastern subtropical oceans, deserts, and higher topography. The ICZ is visible as lower values of terrestrial radiant fluxes in the tropics because the emission is primarily from the cold tops of high clouds. The same clouds strongly reflect solar radiation causing a corresponding solar radiation pattern. The net radiation (**Figure 2(c)**) has a strong latitudinal trend as deduced from **Figure 1**. The primary zonal variations are over the subtropical deserts. These areas are hot (high thermal emission) but reflective (reduced solar absorption) leading to negative net radiation. For thermal balance, energy must be exported from areas of positive to areas of negative net radiation; so, the subtropical deserts maintain their high heat in part because heat energy converges into these deserts. Also, the dry desert surface means the solar energy absorbed mainly heats the surface and overlying air but evaporates little water.

Temperature

In the troposphere and lower stratosphere, absorption and emission of radiation alter the air temperature at a rate of a few degrees per day. This change of air temperature is generally small compared to the difference between the equatorial regions and the polar regions. Hence, the radiant energy absorption and emission do not create large temperature differences between the daylight and night sides of the Earth. Therefore, much about the atmosphere's thermal structure is seen in a zonal mean.

Seasonal averages for winter and summer temperatures are displayed in **Figure 3**. The following properties are evident in the figure:

1. Temperature decreases with increasing height in the troposphere and winter stratosphere. The rate of change with height (equaling minus the lapse rate) is greater in the troposphere and notably less in the stratosphere. The lapse rate is less than the lapse rate for neutral stability; so, the atmosphere is statically stable on the large scale. Temperature increases with height in the tropical lower stratosphere.
2. The tropopause marks the boundary between the stratosphere and troposphere. The zonal mean tropopause is not level, but ranges from 6–8 km (~ 500 – 350 hPa) in polar regions to 16–18 km (~ 100 – 80 hPa) in the tropics.
3. In the troposphere, zonal mean temperature along an isobaric surface decreases toward each pole. The rate of decrease (the meridional gradient) is small in the tropics. This gradient is larger in the middle latitudes (30 – 60° latitude). An exception is the sharp gradient near the Antarctic coast. The gradient is stronger during winter. The temperature change from equator to pole is also greater at the surface than in the middle troposphere.
4. The coldest temperatures are in the winter stratospheric polar region and near the equatorial tropopause.
5. In much of the lower stratosphere, the zonal mean temperature gradient is reversed from the troposphere. The

reversal is evident in much of the tropics and middle latitudes. The main exceptions are the higher latitudes and part of the Southern Hemisphere middle latitudes during winter.

The longitudinal distribution of the temperature illustrated by the 850 hPa level temperatures is shown in **Figure 4**. As anticipated from the terrestrial radiation data, the field has notable zonal symmetry over the oceans. The colder temperatures in middle latitudes tend to be over the eastern sides of the continents during winter. Large ice-covered regions have colder temperatures. During summer, the hottest temperatures are located over the subtropical deserts.

Mass Fields

Geopotential Height Fields

The temperature field is related to the mass fields in several ways. For example, the hypsometric equation demonstrates that the spacing between isobaric surfaces is proportional to the mean virtual temperature of the air between these surfaces. In the troposphere, the vertical distance between any two isobaric surfaces (the 'thickness') is larger in the tropics than outside the tropics. Since the variation of sea level pressure (SLP) over the globe is rather small, this implies that the altitude of an upper air constant pressure surface (500 hPa, e.g.) on average increases from pole to equator.

The zonal and time mean geopotential heights of the 500 and 1000 hPa geopotential height surfaces (Z_{500} and Z_{1000} , respectively) are shown in **Figure 5** for the two extreme seasons. The Z_{500} surface is representative of geopotential height surfaces in much of the troposphere and lower stratosphere. At 500 hPa, higher heights are found in the tropical regions with lowest values near the poles. The gradient between equator and pole is strongest in the middle latitudes and during winter. The Z_{1000} pattern is representative of the mass field near the surface. The zonal average Z_{1000} has lower values near the equator, with higher values in the subtropics (more so in local winter). The lower values in middle latitudes are associated with the midlatitude storm tracks.

Midlatitude Planetary Waves and Storm Tracks

The mass and temperature fields have significant longitudinal variation. Away from the surface, the time mean pattern is characterized by long waves. The time mean Z_{500} (**Figure 6**) has patterns typical of much of the troposphere. Prominent troughs are seen near the midlatitude east coasts of Asia and North America. The temperature field beneath (e.g., **Figure 4**) also has colder values (thermal troughs) near these regions. A weaker geopotential trough occurs over the Mediterranean and Northwest Africa. At the base of each trough the height contours are more closely spaced; from geostrophic wind balance one expects the wind speeds to be relatively stronger there. Ridges are found in between, most prominently in northwestern North America and Europe. In summer, the North American trough remains visible due to the cold air over the Baffin and Greenland ice sheets.

Figure 3 Zonal mean temperature during (a) December–February and (b) June–August. Units are degrees Celsius. The data are from the NCEP/National Center for Atmospheric Research (NCAR) reanalysis period 1979–99. Contour interval is 10 °C.

Consistent with the zonal average distribution (Figure 5) the time average gradient is strongest in middle latitudes. While the gradient has similar strength during winter, during summer the time mean gradient is stronger in the Southern Hemisphere.

Most of the weather in the middle latitudes is created by the traveling frontal cyclones, otherwise known as extratropical cyclones. These cyclones interact with the planetary wave pattern in various ways. These cyclones prefer to form, propagate, and decay in specific regions. Generally speaking, frontal

Figure 4 Temperature at 850 hPa in the two extreme seasons (a) December–February and (b) June–August. Units are degrees Kelvin. The data are from the European Centre for Medium-Range Weather Forecasts ERA-40 reanalysis monthly averaged data from 1979 to 2002. Contour interval is 5 K.

cyclogenesis is favored in three types of regions: near the east coasts of continents, on the lee side of major mountain ranges, and where large-scale surface temperature gradients are strong. Most of these regions coincide with the longwave trough locations. A region of stronger sea surface temperature gradient lies south of Africa and across much of the Southern Indian Ocean. Further south, the near surface temperature gradient is intensified at the edge of Antarctic sea ice. The frontal cyclones generally progress eastward and poleward as they evolve. Figure 6 also shows various archetypal tracks followed by many frontal cyclones. Individual tracks of cyclones vary, but the thicker dashed arrows in Figure 6 indicate the more common paths. In the Northern Hemisphere, cyclones often merge with or supplant the ‘semipermanent’ Aleutian and Icelandic lows that are visible in the SLP field discussed next. The storm tracks show up in the precipitation fields (shown later) as bands of heavier precipitation in the middle latitudes across the oceans. Precipitation also is enhanced where

westerlies encounter mountain ranges of North America and Western Europe.

Sea Level Pressure and Subtropical Highs

The SLP pattern (Figure 7) differs from the mass field pattern at mid and upper troposphere levels (e.g., the Z_{500} pattern of Figure 6). An obvious difference is that the field is noisy over major topographic features because it is based on extrapolating the pressure to sea level. Another difference is the meridional height gradient (created by the meridional temperature gradient through a depth of the atmosphere), which is not so evident at the surface. So, the SLP pattern is more cellular. Another difference is that colder air aloft can result in relatively higher surface pressure near the ground (due to higher average density of the air above compared to an adjacent region). The converse is also true for lower pressure where the air aloft is warmer than the surroundings (so-called

Figure 5 Zonal mean geopotential heights (a) at 500 hPa and (b) at 1000 hPa. Solid line is for December–February seasonal average and dotted line is for June–August. These NCEP/NCAR reanalysis data are from 1979 to 1999.

‘thermal lows’). This relationship is the opposite to that described above for upper air geopotential height because the hypsometric equation relates to the thickness of a layer, not the bottom of a layer.

At the surface one finds prominent high-pressure cells in the subtropics. These cells generally prefer the eastern sides of the ocean basins where thermal and other forcings build higher pressure. For example, equatorward winds on the east side of the subtropical high can drive upwelling of colder subsurface ocean water and the resultant cooler surface is observed to lead strengthening of the high (a result also consistent with potential vorticity reasoning). The colder temperatures foster low stratus clouds, which in turn create a net radiative cooling of the air and additional forcing for the high. The areal extent of the highs is influenced by other factors such as the midlatitude storm tracks and tropical convection. In summer, these factors allow much greater expansion of the subtropical highs in the Northern Hemisphere than in the Southern Hemisphere. A three-way balance between the pressure gradient, Coriolis, and turbulent drag forces implies divergence at a surface high. Surface divergence is consistent with the sinking, and eastern sides of the subtropical highs can be viewed as regions where the

sinking branch of a Hadley cell is enhanced. The sinking is apparent as areas where upper-level divergent winds converge (shown below). The tropical convection, mainly equatorward and to the west of the subtropical high, feeds the circulation supporting the high; this link is visible in the divergent winds.

Wind Fields

Zonal Velocity

The zonal wind is directed positive when blowing toward the east. Outside the equatorial region, the mass and wind fields are in approximate geostrophic balance. The meridional gradient seen in the tropospheric geopotential height fields implies a westerly wind which is stronger in middle latitudes. At the surface, comparatively weak winds are expected.

The thermal wind relation states that vertical *shear* of the zonal wind is proportional to the meridional gradient of temperature and inversely proportional to the Coriolis parameter. The temperature gradient in much of the troposphere is directed equatorward, an orientation implying westerly wind shear. Since the tropospheric temperature gradient is

Figure 6 Geopotential height of the 500 hPa surface (contours) in the two extreme seasons (a) December–February and (b) June–August. Units are in meters. The data are from the European Centre for Medium-Range Weather Forecasts ERA-40 reanalysis averaged data from 1979 to 2000. Also plotted are general indicators of the frontal cyclone storm tracks (dashed arrows) where a wider arrow indicates more frontal cyclone passages than for a thinner arrow. Frontal cyclone storm tracks shown merge information from these sources:

 Dos Santos Mesquita (2008) Climatological properties of summertime extra-tropical storm tracks in the Northern Hemisphere. *Tellus* 60A: 557–569.

stronger in middle latitudes, one expects the westerly shear to be stronger there as well. The temperature gradient reverses in the tropical and middle latitudes of the lower stratosphere implying easterly shear. Therefore, one anticipates westerly winds to increase with height in the troposphere and to decrease above, in the lower stratosphere. In short, the stronger westerly winds tend to occur at tropopause level.

Another constraint on the zonal wind is angular momentum balance. If the winds at the surface were everywhere

westerly (say) then those winds would apply a net torque upon the surface of the Earth. A net westerly torque would speed up the rotation of the Earth and the days would be getting shorter. However, the angular momentum of the Earth is essentially constant. So, one expects that areas of easterly winds are balanced by areas of westerly winds at the surface.

The zonal mean of the zonal wind is shown in [Figure 8](#) for winter and summer. Areas that are shaded indicate easterly winds. The following properties are evident in the figure.

Figure 7 SLP contours in the two extreme seasons (a) December–February and (b) June–August. Units are in hectoPascals. Contours use 4 hPa interval. The data are from the European Centre for Medium-Range Weather Forecasts ERA-Interim Reanalysis averaged data from 1989 to 2010.

1. The surface winds are generally easterly in the tropics, which cover approximately half of the surface area of the globe. The surface winds are primarily westerly in the middle latitudes.
2. The winds generally gain a westerly component with elevation. For the tropical troposphere, the easterly wind decreases with increasing elevation. For much of the middle latitudes, the westerly wind increases with height until the tropopause. Above, the vertical shear reverses and the westerlies decrease with increasing height. The principal exceptions are the high latitudes in winter. These properties, including the exceptions, are anticipated from the temperature gradients shown above (Figure 3).
3. In the high latitude, winter stratosphere, westerly winds increase with height. It is difficult to see with the vertical coordinate chosen, but these westerly winds are associated with the polar night jet. This jet reaches maximum speed in the upper stratosphere (10–30 hPa level).
4. The subtropical jets are prominent maxima at the midlatitude tropopause. These jets are stronger and migrate to a lower latitude in winter. In the Southern Hemisphere during winter, strong winds of the polar night jet extend into the troposphere creating the impression that there are two tropospheric jets on upper-level isobaric charts. During northern summer an easterly jet is visible at tropopause level just north of the equator.

Meridional Circulations

The meridional wind at a specific location can often be comparable in magnitude to the zonal wind. However, if the meridional wind is geostrophic, then a zonal average of the meridional wind is the integral (with respect to longitude) of

Figure 8 Zonal mean zonal wind (solid contours; in m s^{-1}) with potential temperature (dashed contours; in Kelvin) for seasonal averages (a) December–February and (b) June–August. Areas of easterly winds are shaded. NCEP/NCAR reanalysis data from 1979 to 1999.

a longitudinal derivative. Unless a mountain intercepts the integral path, this integral must be zero because the integral completes a circuit. Since the total wind is nearly in geostrophic balance outside the tropics, the zonal mean meridional wind is very small outside the tropics.

Since the observed lapse rate is less than the dry adiabatic lapse rate, it follows that vertical motions are resisted. One consequence is that vertical motions are far smaller in magnitude than are horizontal motions on this large scale. Large-scale vertical motion cannot be directly measured since it is smaller

Figure 9 Zonal mean meridional circulations for (a) December–February and (b) June–August. Some of the large vectors for $p > 700$ hPa over Antarctica may not be meaningful. Vectors based on NCEP/NCAR reanalysis data from 1979 to 1999.

than the errors of the observing systems. Vertical velocity can be estimated indirectly from quantities that are measured with some confidence. One procedure is to merge measured meridional winds in the tropics with meridional winds elsewhere estimated from an equation for angular momentum

balance and then deduce a stream function in the meridional plane. An alternative procedure is to input observed fields into a primitive equation general circulation model and let the model deduce the vertical motion. The latter procedure obtained the motions shown in Figure 9.

The zonal mean motions in the meridional plane have the following properties:

1. The motion is organized into distinct patterns commonly referred to as meridional cells. The most prominent cells occur in the tropics and are often named the 'Hadley' cells. In the middle latitudes of each hemisphere is found a much weaker circulation usually labeled the 'Ferrel' cell.
2. The meridional cells are much stronger during winter both in terms of the areal extent they occupy and the vigor of the circulation. The winter Hadley cell has significant flow across the equator.
3. In the Hadley cell, air circulates in an intuitive sense: rising motion occurs where the mean temperature through the depth of the atmosphere is warmer, sinking motion where it is cooler. The temperature distribution over the globe is statically stable in the dry sense. However, in the lower tropical troposphere the air is very moist and nearly neutral with respect to a pseudoadiabatic lapse rate. The upward motion of the Hadley cell is driven by latent heat release as water vapor is converted into precipitation. So, one expects precipitation to be maximum in the tropics. In order to overcome the moist static stability and entrainment as air parcels rise into the upper tropical troposphere, the rising motion is embedded within thunderstorms. These thunderstorms occupy a very small fraction (about 0.5%) of the tropical surface area. Air parcels in the poleward moving branch of the Hadley cell cool radiatively, as their potential temperature decreases these parcels sink.
4. In the Ferrel cell, air appears to rise where temperatures are cooler and sink where they are warmer. This Eulerian mean motion should not be confused with the actual paths of air parcels. In middle latitudes parcel motions are strongly influenced by baroclinic waves. The zonally varying (eddy) flow associated with baroclinic waves has comparable meridional and zonal components. When an average is taken around a latitude circle at constant pressure, the northward and southward motions nearly cancel and the resulting mean has the sense given by the Ferrel cell. Such a mean creates a misleading picture of the motions of air parcels. However, if an average is taken along constant entropy surfaces, the resulting zonal mean in isentropic coordinates shows a meridional circulation having rising in the subtropics and sinking at high latitudes, i.e., the same sense as the Hadley circulation. The pattern in isentropic coordinates follows from the mass distribution of baroclinic eddies: in an upper isentropic layer slightly more mass is heading poleward than equatorward, vice versa for a lower layer. Therefore, in isentropic coordinates the motion is more intuitive: rising motion at lower latitudes and sinking motion at higher latitudes. Even though the Ferrel cell does not reflect the actual motion of parcels, the Ferrel cell does depict components of the motion necessary to counteract eddy fluxes of heat and momentum that would otherwise destroy thermal wind balance. (Eddy heat fluxes reduce the meridional temperature gradient while eddy momentum fluxes increase the westerly vertical shear. Planetary angular momentum and vertical adiabatic heat transports by the Ferrel cell can counteract these eddy fluxes.)
5. The radiative energy distribution requires a meridional circulation to transport heat poleward. The meridional motions of the Hadley cell transport the same mass poleward as southward (ignoring the mass due to moisture). The Hadley cell has a net heat transport because the upper-level air has higher moist static energy than does the lower-level air. In the case of the Ferrel cell, the frontal systems have strong heat fluxes that can be deduced from westward tilts with height of the trough and ridge axes of these waves.

Divergent Tropical Circulations

The Hadley cell upward motion is part of the divergent winds of the tropics. Diverging arrows in [Figure 10](#) imply rising motion below. Following the divergent wind vectors appears to connect areas of preferred rising with the sinking above the eastern sides of several subtropical highs. Some divergent winds are poleward and thus consistent with the Hadley circulation at 200 hPa. The strongest areas of divergence in [Figure 10](#) overlie Southeast Asia, Indonesia, and Amazonia. In northern summer, the Southeast Asian Monsoon is prominent. The figure also shows prominent east–west motion in the Pacific that is generally referred to as the 'Walker' circulation. The Walker circulation apparently connects rising motion (and thus precipitation) over the far Western Pacific with enhanced sinking over the east side of the subtropical high in the Eastern Pacific. The rising air is fed by low-level convergence that results from ageostrophic motions that occur for relatively low surface pressure ([Figure 7\(b\)](#)). Low-pass filtered observations show a correlation between heavier precipitation in Indonesia, lower pressure there, and stronger Pacific subtropical highs.

Subtropical Jet Streams

Zonal variations of the subtropical jet streams are linked to several phenomena discussed above. The time mean wind speed is plotted in [Figure 11](#). Consistent with geostrophic balance, the winds are stronger where the horizontal gradient of time mean geopotential height is stronger. That gradient was stronger at the bases of longwave troughs in geopotential (and temperature) near the east coasts of Asia, North America, and Australia (during local winter).

The Northern Hemisphere subtropical jet streams have a larger relative maxima near the east coast of Asia than the corresponding part of North America. These maxima are much stronger during winter (December–February (DJF)). The downstream end of each of these maxima is further poleward than the upstream end. Consequently, two jets occur over both the Eastern Pacific and the Eastern Atlantic, one velocity maximum south of the other. This combination of velocity maxima contributes to sinking above the east side of the SLP subtropical highs.

In the Southern Hemisphere the jet streams are more zonally oriented. In summer there is a tendency for stronger flow south of Africa. In winter (June–August (JJA)) the stronger winds occur east of Australia. As anticipated from the zonal mean ([Figure 8](#)) there is a secondary maximum at a higher

Figure 10 Time mean divergent wind (arrows) and velocity potential (contours) at 200 mbar during (a) December–February and (b) June–August. The longest arrow on the map is approximately 7 m s^{-1} and the contour interval is $2 \times 10^6 \text{ m}^2 \text{ s}^{-1}$. NCEP/NCAR reanalysis data from 1979 to 1999.

Figure 12 Cloud amount during December–February (left column) and June–August (right column). (a) and (e) Total amount at all levels. Estimates of average cloud amounts assigned to three general elevation ranges are also shown. (b) and (f) High clouds in the range of 50–440 hPa. (c) and (g) Middle tropospheric clouds in the range of 440–680 hPa. (d) and (h) Low-level clouds below 680 hPa pressure surface elevation. Cloud amounts based on satellite estimates of the fraction of 5 km wide pixels report cloud in each 280 km wide region. Geostationary and polar orbiting satellite data used, leading to some artificial boundary effects (e.g., Indian Ocean). Data are provided by the International Satellite Cloud Climatology Project (ISCCP) D2 monthly means combined from the July 1983 through June 2008 time period. If reproduced in grayscale, dark gray form few clouds, lightest gray for a middle amount of clouds for each indicated range, and light inside darker gray for higher amounts in the range.

Data maintained by the ISCCP research group at the NASA Goddard Institute for Space Studies, New York, NY, on January, 2005. Reproduced from Rossow, W.B., Schiffer, R.A., 1999. Advances in understanding clouds from ISCCP. *Bulletin of the American Meteorological Society* 80: 2261–2288.

latitude (in the Southern Indian Ocean and south of New Zealand). The more southerly maxima are a downward expression of the stratospheric polar night jet.

The divergent winds of the Hadley cell advect planetary angular momentum poleward and thereby strengthen the subtropical jets. As shown in Figure 10, the tropical circulation is not uniform with longitude but rising motion is enhanced in certain regions. The poleward motion consequently strengthens the subtropical jet in favored locations. Near the east coast of Asia, divergent winds blowing northward from the Indonesia region during northern winter build higher pressure to the southeast of the Asian longwave trough. The higher pressure there amplifies the height gradient on the southeast side of that trough making the jet stronger. The divergent flow southward from the Indonesia region contributes to the stronger jet over Australia by similar reasoning.

Moisture

Clouds

Figure 12 shows the distribution of clouds in terms of cloud amount. Cloud amount is a measure of the fractional area of the sky covered by clouds. Figure 12 shows the total cloud and the cloud amounts in three ranges based on an estimate of the pressure at the top of each cloud. Clouds at one location often occur at multiple levels, however, satellites observe the topmost layer. Since satellites observe the highest clouds, the seasonal means of the middle and low clouds shown in Figure 12 have been augmented by other observations of humidity beneath higher clouds over some land areas.

Areas of rising motion deduced from the velocity potential (Figure 10) are collocated with some, but not all, of the cloudy regions. The broad regions of rising motion deduced from Figure 10 correspond with generally smaller cloudy regions with some details in the cloud structure related to the topography. Generally, the match between Figures 10 and 12 is better for deep clouds (areas having higher cloud amounts at all levels). Some areas of sinking deduced from the velocity potential over the eastern ocean basins are also near persistent clouds, but these are low clouds.

The following properties are evident in the seasonal mean cloud amounts:

1. Deep clouds are found along the ICZ. The clouds tend to occupy a narrower band over the oceans (e.g., the Eastern Pacific) and are broader over the large tropical landmasses (e.g., Southeast Asia). The impact of the ICZ cloudiness on radiation was noted in Figure 2.
2. Cloud amounts are low over subtropical deserts but high over the adjacent east sides of the subtropical oceans. These clouds are confined to low elevation and tend to be more prominent during local spring (Southern Hemisphere) or summer (Northern Hemisphere).
3. Cloud amounts are high along the midlatitude storm tracks (Figure 6). In the Northern Hemisphere, the high and middle level cloudinesses along the storm tracks are notably greater during winter. The corresponding seasonal change in the Southern Hemisphere is less obvious.

Precipitation

Precipitation is linked to the general circulation in several ways. Figure 13 shows the zonal mean distribution of precipitation rate. The largest precipitation rate occurs in the tropics along the ICZ and is associated with the rising branch of the Hadley cells. The peak value migrates to about 10–15° latitude in the summer hemisphere (on a zonal average); a migration consistent with the dominance of the winter hemisphere Hadley cell (Figure 9). In some seasons, two equatorial maxima are found whose explanation becomes clear when time mean fields are consulted. Subtropical sinking motion seen in the meridional cells suppresses the precipitation rate. Secondary maxima occur in middle latitudes that are superficially linked to the rising branch of the Ferrel cells, but are more properly associated with the extratropical cyclones. While the cloudiness (Figure 12) is high in high latitudes precipitation is light, the colder air does not contain as much water vapor mass as in the tropics.

The zonal mean Hadley circulation implies transport of moisture from the subtropics toward the ICZ. The vigorous upward motion near the equator is driven by precipitation formed within thunderstorms that cover only a small fraction of the tropics at any one time. The time mean precipitation, Figure 14, shows tropical precipitation matching the larger cloud masses (especially high cloud) shown in Figure 12. Therefore, precipitation rate is higher over tropical land areas and regions of warmest sea surface temperature (i.e., Western Pacific). During southern summer, precipitation is greatly enhanced over the Southern Indian Ocean and tropical landmasses, while over the Eastern Pacific the ICZ remains north of the equator resulting in the double maximum seen in the zonal average during DJF (Figure 13). The South Pacific Convergence Zone is also prominent; part forms the ICZ of the Western Pacific and part is the northwest–southeast oriented line of higher precipitation across the South Pacific.

Higher time mean precipitation rates (Figure 14) are found along the midlatitude storm tracks (Figure 6) with larger

Figure 13 Zonal mean precipitation rate in millimeters per day for December–February (solid line) and June–August (dotted line). Climate Prediction Center Merged Analysis of Precipitation (CMAP) 1979–99 data used. Data provided by the NOAA/OAR/ESRL PSD, Boulder, Colorado, USA, from their Web site at <http://www.esrl.noaa.gov/psd/>.

amounts near the start of the tracks and where the flow encounters topography (west coasts of the Americas).

Broad Summary

The observed time and zonal mean properties of the large-scale primary atmospheric variables were briefly described. Above the planetary boundary layer, these variables tend to have stronger meridional than longitudinal variation, thereby validating the use of zonal average depictions. The zonal variations are related to surface properties (land versus sea, ice versus vegetation, surface temperature gradient) and major topographic features. Seasonal changes were described; the most general comment is that seasonal variation is less in the Southern Hemisphere compared to the Northern Hemisphere.

Synopsis

Teleconnections refer to the climate variability links between non-contiguous geographic regions. Teleconnection patterns are extracted from analysis of the sea-level/tropospheric pressure variations on monthly (and weekly) timescales. The methods used in extraction of teleconnection patterns are discussed and applied to recent period data. Teleconnections are especially well-developed in Northern winter, when they strongly influence subseasonal variability, notably, in surface temperature and precipitation; the stratospheric and SST links are also noted. The patterns in boreal summer are shown, as are Southern Hemisphere teleconnections. Aspects of tropical–extratropical teleconnections are discussed, along with the relationship between annular modes and teleconnections. Finally, a teleconnection analysis with pentad (5-day averaged) data is presented to initiate discussion of teleconnection evolution.

Introduction

The term teleconnection is often used in atmospheric sciences to describe the climate links between geographically separated regions. The remote region need not exhibit fluctuations of the same sign in order to be ‘teleconnected.’ In fact, the interesting teleconnections often involve contemporaneous variations of opposite signs. Climate analysis is facilitated by the construction of a teleconnection map, which describes the linkage between a region of interest (a base point) and all other points in the domain that are farther than the decorrelation length scale of the variable. Teleconnection maps thus provide information about the structure of recurrent climate variability, especially its correlation-at-a-distance features. The maps are useful because climate variability is often manifest with such structure: for example, winter variations in temperature and rainfall over southern Europe and the Iberian Peninsula are frequently opposite to those over northwestern Europe and Scandinavia.

Teleconnection maps were first constructed for meteorological parameters measured at the Earth’s surface, such as the atmospheric pressure. The selection of the base point is a critical first step, and was, historically, guided by the investigator’s insights and interests. Today, base points can be selected more objectively, and the robustness of teleconnection maps can be ascertained by independent analyses. The statistical correlation of the fluctuations provides a measure of the teleconnection strength. The structure and strength of the teleconnection patterns change with season, altitude, choice of variable, and even temporal averaging of data. There are interesting differences between the hemispheres too, in part, due to the presence of extensive continents and mountainous zones in the Northern Hemisphere (NH). Teleconnectivity in the NH winter circulation has been extensively analyzed as teleconnections account for a significant portion of the winter variance in this region.

Climate teleconnections are present in observations that have been averaged in time over a period that is long enough to suppress the day-to-day weather fluctuations, but short enough to retain the seasonal-to-interannual component of climate variability. Although teleconnection patterns often evolve on submonthly timescales (~weeks), their spatial patterns are characterized in monthly and seasonal data. Monthly averages

are typically used since a month is longer than the period of most large-scale synoptic waves in the troposphere. Climate teleconnections thus highlight the ‘standing’ component of low-frequency variability – one with geographically fixed nodes and antinodes. The connectivity of remote regions manifest in the teleconnection map indicates the potential significance of remote forcing in the generation of regional climate anomalies. A teleconnection map based on contemporaneous correlations however cannot, by itself, discriminate between the forcing and response regions.

Although the structure of the prominent teleconnection patterns has been known for some time, the reasons for their origin are not yet well understood. For example, the mechanisms that excite and sustain the North Atlantic Oscillation (NAO) – one of the notable and earliest discovered patterns – are still being investigated. In the context of such investigations, it has been questioned if the teleconnection patterns that are typically regional (e.g., NAO), robustly portray the spatial structure of variability from the viewpoint of elucidation of the underlying dynamical processes.

Such concerns are relevant since the canonical teleconnection patterns typically represent the mature phase of variability. The mature-phase pattern, however, need not resemble the nascent-phase structure, which may be more revealing of the excitation mechanism. Identification of the evolution process from analysis of the mature-phase structure is thus difficult. The spatial imprint of variability captured by a teleconnection pattern can also be ineffective in revealing the underlying mechanisms if the region in question is the locus of two temporally independent physical and/or dynamical processes. While cautionary, these remarks do not call for a radically new analysis paradigm. Instead, they point to the need for more comprehensive analysis of variability, particularly, in the spatiotemporal domain, to facilitate insights into the evolutionary process. While in-depth analysis of this kind is beyond the scope of this article, it is important to let the reader know that contemporary teleconnection research is rooted in spatiotemporal analyses.

Additionally, while teleconnectivity has historically been identified from assessment of the correlation between some defined base point and distant points in the domain, not all

teleconnection patterns are uncovered from such analysis. Examples on subseasonal to seasonal timescales include the Madden–Julian Oscillation (MJO) and the annular modes, both of which are briefly discussed in subsequent sections. An example on interannual timescales is the El Niño–Southern Oscillation (ENSO), which impacts climate around the globe.

Analysis Method

Teleconnection patterns can be extracted from correlation analysis and from the calculation of principal components (PCs), among other techniques. Both methods have been widely used in climate research, and each offers some advantages.

Correlation

Correlation analysis is the more straightforward of the two methods. Consider a meteorological field such as geopotential height that denotes the height of an isobaric surface in the atmosphere. Geopotential height, ϕ , is a function of longitude and latitude, and assume that it is defined at M grid points; ϕ_i represents height at the i th longitude–latitude grid point. Geopotential height is also a function of time, and its monthly mean value is assumed to be available for several winters (N winter months). Interest in the variability of climate leads to the consideration of departures of monthly mean heights from their calendar month climatologies, with prime (') denoting the departures; $\phi'_{i,k}$ representing the height departure at the i th grid point in the k th month. The correlation in height departures at two grid points, i and j , is denoted by H_{ij} , and defined as

$$H_{ij} = \frac{\sum_{k=1}^N \phi'_{i,k} \phi'_{j,k}}{\left(\sum_{k=1}^N \phi'^2_{i,k} \right)^{1/2} \left(\sum_{k=1}^N \phi'^2_{j,k} \right)^{1/2}}$$

Knowledge of the correlation matrix, $\mathbf{H}$, can be used to construct a teleconnectivity map ($\mathbf{T}$) that objectively identifies the base points associated with various teleconnection patterns. The map is constructed by associating the magnitude of the strongest negative correlation between a grid point and all others with that grid point, i.e., $T_i = |\text{most negative member in the } i\text{th row of the correlation matrix } \mathbf{H}|$. The local maxima in this map ($\mathbf{T}$) identify the potential base points. Linkage between the neighboring base points is assessed by examining the sites of their strongest negative correlations. A cluster of linked base points constitutes the core of the teleconnection pattern, and three prominent patterns are identifiable using this technique.

Teleconnection Map

Climate teleconnections were first investigated in the sea-level pressure (SLP) field. SLP is however an ill-defined quantity over land, particularly near the mountains; it can moreover be influenced by local meteorological processes. Teleconnectivity is thus better analyzed in upper-air data, which became available since the mid to late 1940s. The preferred analysis variable in recent decades has been the geopotential height – a measured quantity, whose horizontal and vertical gradients are proportional to the wind and temperature, respectively. Northern winter is the preferred season for teleconnection

analysis in view of the pronounced climatological stationary waves (from impressive mountains and continents in the NH) that impart a significant ‘standing’ component to the interannual fluctuations.

Figure 1(a) shows the teleconnectivity in the 500-mb geopotential height field during Northern winter. The map is constructed from correlation analysis of December, January, and February (DJF) height anomalies from 0 to 90° N for the 1979–2008 period; the data are from NOAA’s Climate Forecast System Reanalysis (CFSR). This recent reanalysis takes advantage of the latest advances in data assimilation and incorporates important data from the satellite era, and thus only extends back to 1979. This figure is comparable to **Figure 7(b)** in the pioneering study by [Wallace and Gutzler \(1981\)](#). It identifies three major teleconnection patterns in the NH: the NAO, the North Pacific Oscillation/West Pacific pattern (NPO/WP), and the Pacific–North America (PNA) pattern. The NAO and NPO/WP each consist of two base points over the Atlantic and Pacific basins, respectively. The PNA, as identified by [Wallace and Gutzler \(1981\)](#), consists of four base points: the subtropical Pacific near the dateline, the Aleutians, interior northwestern North America, and the southeastern United States. Note, however, that the fourth base point over southeastern United States is missing in **Figure 1(a)**.

This brings to light an issue regarding the stability of teleconnection patterns. Changing the domain and time period of the analysis can introduce some differences: Besides the missing PNA center, there are other differences between the seminal analysis of Wallace and Gutzler and **Figure 1(a)**. The NAO-related pattern exhibits a noticeable eastward shift, as does the third PNA center. Note, data set differences are unlikely to be the origin as the large-scale rotational flow is similarly represented in atmospheric data sets. While notable, the teleconnectivity differences are viewed as modest considering the nonoverlapping periods of the two analyses. This assessment is supported by **Figure 1(b)**, which shows the teleconnectivity map from a similar analysis of longer period data (1949–2009), one encompassing the previous nonoverlapping periods. While the NAO centers and the third PNA center here are more in accord with the Wallace and Gutzler analysis, the fourth PNA center remains indiscernible. Interestingly, the NPO/WP centers of action are also not identifiable in the longer period analysis. Even so, the overall structure of the teleconnectivity map is similar in **Figure 1(a)**.

The correlation analysis reveals the base points of a teleconnection pattern. An index constructed using the magnitude of fluctuations at the base points is used to track the pattern amplitude. For example, the PNA index is defined as

$$\alpha_{\text{PNA}}(k) = \frac{1}{3} \left(\frac{\phi'_{A,k}}{S_A} - \frac{\phi'_{B,k}}{S_B} + \frac{\phi'_{C,k}}{S_C} \right)$$

where A, B, and C are the marked base points of the PNA pattern (**Figure 1(a)**). S_i in the above definition denotes the standard deviation of height anomalies at the i th base point. Likewise an index can be constructed for the NAO- and NPO/WP-related patterns, using two base points in each case.

Correlation analysis is a physically intuitive and objective method for identifying climate teleconnections but the obtained patterns may not be independent, especially, if spatial

Figure 1 (a) 500-mb geopotential height teleconnectivity map for Northern Hemisphere winter (DJF), comparable to seminal **Figure 7(b)** in Wallace, J.M., Gutzler, D.S., 1981. Teleconnections in the geopotential height field during the northern hemisphere winter. *Mon. Weather Rev.* 109, 784–812. Contour/shading starts at a correlation of 0.5 and increases at 0.1 intervals. Points A, B, Bb, and C refer to the centers of actions of the PNA pattern. Points B and Bb are generally associated with the Aleutian Low center of action. (b) 500-mb geopotential height teleconnectivity map for Northern Hemisphere winter (DJF), comparable to seminal **Figure 7(b)** in Wallace, J.M., Gutzler, D.S., 1981. Teleconnections in the geopotential height field during the northern hemisphere winter. *Mon. Weather Rev.* 109, 784–812. **Figure 1**, except for a prolonged analysis period from 1949 to 2009. Contour/shading starts at a correlation of 0.5 and increases at 0.1 intervals. Points A, B, Bb, and C refer to the centers of actions of the PNA pattern. Points B and Bb are generally associated with the Aleutian Low center of action. DJF, December, January, February.

structures overlap. This, for instance, is the case in the Pacific, where three prominent patterns – PNA, WP/NPO, and the ENSO response (shown later) – overlap to varying extent in the extratropical sector. Not surprisingly, the correlation method proved unsuccessful in capturing the ENSO response in the extratropics as a teleconnection pattern. Could this be a consequence of focusing on analysis of midtropospheric variability? The 500-hPa level – a level of near-zero divergence – is, perhaps, not the level of choice for identifying tropical–extratropical interactions instigated by deep convective heating in the Tropics. Horizontal divergence associated with deep convection, such as during El Niño winters, is usually strongest in the tropical upper troposphere (~ 200 hPa). The associated midlatitude response, on the other hand, is quasi-geostrophic in character, and hence approximately nondivergent. Tropical–extratropical interactions are thus best diagnosed at a pressure level that captures the divergent outflow in the Tropics and that is near a nondivergent level in the extratropics. The 200-hPa level meets these criteria to a large extent.

Repeating the correlation analysis of height fluctuations at 200 hPa did not yield any new information on teleconnectivity. In particular, no new base points were identified and the ENSO response in the extratropics remained unidentified as before.

Principal Component Analysis

Principal component analysis (PCA) is an elegant and widely used method for determining the structure of recurrent variability. A common name for it is empirical orthogonal function (EOF) analysis. This method also analyzes the structure of the correlation matrix – the covariance matrix is preferred, though –

but focuses on regions that account for a substantial portion of the temporal variance rather than just those which exhibit strong negative correlations with distant points in the domain. In contrast with the previous method, the technique yields both the spatial patterns of recurrent variability and the extent to which these are present, or projected, in the observed anomaly record. The projection, or amplitude, is called the PC while the spatial pattern is referred to as the loading vector (LV) in the technical literature.

Recurrent variability patterns identified from PCA are spatially and temporally independent, or orthogonal. Such relationship among patterns is often helpful in investigating the origin and governing mechanisms of variability but can be relaxed in one of the dimensions – space or time – if the orthogonality constraints prove restrictive. For example, it is conceivable for two temporally independent variability patterns to have overlapping spatial structure. Imposition of temporal and spatial orthogonality constraints in this case may not lead to a physically meaningful analysis.

The EOF analysis results in a series of spatial patterns, or LVs, each one explaining successively smaller portion of the total temporal variance. One can view these recurrent patterns as teleconnection patterns. The pattern amplitude is given by the time-dependent PC. The anomaly record can be reconstructed by summing the product of the spatial patterns (LVs) and their PCs.

Rotated Principal Component Analysis

PCA provides an efficient and unique characterization of recurrent variability in terms of a small number of uncorrelated spatial patterns. The patterns are chosen so that each one

successively explains the maximal residual variance in the anomaly data set. For instance, the leading PC is obtained by requiring that it maximizes the sum of the squared temporal correlation between itself and the anomaly time series at all spatial points in the domain. The resulting PCs are temporally orthogonal while the LVs are spatially orthogonal. Spatial orthogonality can however be restrictive and, in many cases, undesirable, as discussed earlier: Although the leading LV is not directly impacted, subsequent LVs are often constrained to have predictable geometric relationships vis-a-vis the leading pattern; domain geometry, thus, becomes an influencing factor, itself.

For these and other reasons, a variant of PCA, called the rotated principal component analysis (RPCA), has become popular since it yields patterns that are no longer constrained to be spatially orthogonal; domain geometry is thus much less influential; rotated PCs continue to be temporally orthogonal, though. The linear transformation (or solid rotation) of PCs that is widely used in meteorology is called the 'varimax' rotation. It is determined by the requirement that the variance of the squared correlations between each rotated PC and the original time series be maximized. Focusing on the variance, rather than sum (as in unrotated analysis), of the squared correlations increases spatial discrimination, and facilitates interpretation of the obtained patterns.

Typically, only a subset of the leading PCs is rotated. Although several criteria exist to guide the choice of this subset, the sensitivity of results to the rotated number offers good practical guidance. In most meteorological applications, 8–10 of the leading PCs are rotated; in most applications reported here, the number is eight.

A more technical discussion of RPCA can be found in Barnston and Livezey where RPCA is advanced as a preeminent method for defining and monitoring of teleconnection patterns.

Empirical Orthogonal Teleconnection

An alternate method for identifying the teleconnection patterns is empirical orthogonal teleconnection (EOT) analysis, developed by Van den Dool et al. (2000) EOT analysis is conducted by finding a base point in the domain that explains the most variance at all the other points combined, using linear regressions. This leading spatial pattern is defined from the linear regression coefficients of this base point, while its time series is simply the raw time series at the base point. Subsequent patterns are obtained by repeating this procedure on a reduced data set, from which the first pattern has been linearly removed.

The analysis results in a series of spatial patterns, or EOTs, that are not constrained to be spatially orthogonal, but whose time series are independent. In this way, it is similar to RPCA. Other than the inherent simplicity, EOT analysis holds another advantage over RPCA: In RPCA, only a small subset of PCs are subject to rotation; no such truncation is required in EOT analysis.

Northern Winter Teleconnections from RPCA

The leading patterns of recurrent height variability are extracted from RPCA and shown in Figure 2. The DJF anomalies during 1979–2008 winters were analyzed in the 30° S–90° N domain. Analysis was conducted at the 200-hPa level in order to also

capture the tropical–extratropical interactions (e.g., ENSO related) that are prominently manifest in the upper troposphere, for reasons stated earlier. Height anomalies were multiplied by the square root of the cosine of latitude to achieve grid-area parity, which prevents polar regions with many more points on a regular latitude–longitude grid, from unduly influencing the analysis. The covariance, rather than correlation, matrix was analyzed so that regions with large variance can exert greater control on the analysis outcome. The eight leading PCs were rotated using the varimax criterion. The PCs are normalized and dimensionless and the spatial patterns (LVs) show nothing but the regression of the PCs onto the 200-mb height field.

The leading pattern explains ~15% of the monthly variance in the domain, with two centers of action in the Atlantic sector. Note the spatial similarity to the Atlantic Basin teleconnectivity structure in Figure 1, sans its earlier noted eastward shift. This leading pattern is clearly the NAO. Its structure is consistent with its historical characterization as a north–south dipole in SLP that represents out-of-phase fluctuations of the Icelandic Low and Azores High. For example, Hurrell's monthly NAO index is constructed from the difference of normalized SLP anomalies at Ponta Delgada, Azores and Stykkisholmur, Iceland; the NAO pattern depicted in Figure 2 is thus in its positive phase, which strengthens the regional winter circulation features. The identification of NAO as the leading pattern in the 200hPa analysis is important both for explanation of regional variance and for showing NAO variability to be temporally orthogonal to the other NH variability patterns. The NAO pattern is manifest on timescales ranging from subseasonal to decadal, as seen in Figure 3. The NAO pattern is closely linked with meridional excursions of the Atlantic jet, and related storm track displacements; northward in the positive phase of the pattern.

The second, third, and fourth leading patterns all have centers of action in the Pacific sector, attesting to RPCA's skill in separating overlapping variability structures. The second leading pattern represents higher geopotential heights in all sectors of the northern subtropics, but especially over the central/eastern Pacific. Higher upper-level heights are typically associated with a warmer air column underneath, since the atmosphere is in hydrostatic balance. The pattern of variability is thus associated with a warming of the Tropics, such as during El Niño winters. The presence of a subtropical ridge to the southeast of the Hawaiian Islands is indicative of linkage with ENSO, for deep convection in this tropical Pacific sector and the related divergent outflow are linked with the development of an upper-level anticyclonic circulation in the subtropics. The subtropical ridge also reflects the southeastward extension of the Asian-Pacific jet in El Niño winters. The ENSO pattern is also characterized by an east–west dipole near North America with a negative anomaly along and off the west coast and a positive anomaly near the south shore of Hudson Bay.

The PC associated with this spatial pattern exhibits inter-annual variability and is correlated ($r = 0.6$) with the Niño 3.4 index, which is the average sea surface temperature (SST) anomaly in the central-eastern equatorial Pacific (5° S–5° N, 170–120° W) and operationally used to define the state of ENSO. While this pattern, which explains ~13% of the monthly winter variance, is characterized as the ENSO response, the related PC exhibits some long-term trend as well.

Figure 2 The four leading teleconnection patterns from a rotated EOF analysis conducted on monthly 200-mb wintertime height anomalies: (a) NAO, (b) ENSO related, (c) NPO/WP, and (d) PNA. The domain of the analysis is 30°S – 90°N . Contour/shading interval is 10 m; the zero contour is suppressed. Percentage of explained variance: (a) 14.6, (b) 12.5, (c) 11.4, (d) 11.1. NAO, North Atlantic Oscillation; ENSO, El Niño–Southern Oscillation; NPO/WP, North Pacific Oscillation/West Pacific; PNA, Pacific–North America.

It is remarkable that RPCA of upper-tropospheric heights can identify the ENSO-related height pattern without any reference to the underlying SST variability. Note that teleconnection analysis of the 200-hPa height variability in the same period was unsuccessful in this regard.

The third and fourth leading patterns of Northern winter height variability each explain $\sim 11\%$ of the monthly variance. The third leading pattern in **Figure 2** consists of a north–south dipole in the North Pacific with a downstream height anomaly over eastern North America centered over Hudson Bay. This pattern is referred to as the NPO/WP pattern as the related SLP pattern (shown later) closely resembles the NPO, a recurrent subseasonal variability pattern in SLP, first identified by Walker

and Bliss in 1932. The ‘West Pacific’ part of the name is from Wallace and Gutzler’s teleconnection analysis of 500-hPa heights. The NPO/WP pattern can be viewed as the NAO analog in the Pacific Basin: both patterns describe subseasonal height fluctuations in the jet-exit regions of the climatological jets streams. The fluctuations have a meridional dipole structure with a stronger polar center in both cases, and linked with meridional displacements of the jets and related storm tracks. A multivariate description of the NPO/WP pattern and its similarity with the NAO can be found in Linkin and Nigam.

The fourth leading pattern is the PNA, defined by the coherent arcing pattern of height fluctuations of alternating signs, beginning with the center over Hawaii and followed by

Figure 3 The principal component time series for each pattern is shown. (a) NAO, (b) ENSO related, (c) NPO/WP, (d) PNA. Note that there are only values for the DJF season. NAO, North Atlantic Oscillation; ENSO, El Niño–Southern Oscillation; NPO/WP, North Pacific Oscillation/West Pacific; PNA, Pacific–North America.

centers over the tip of the Aleutians, northwestern North America, and Southeast United States. In the positive phase (depicted), the pattern consists of positive height anomalies over northwestern North America. In the Pacific sector, the height anomalies represent eastward displacement and meridional focusing of the Asian-Pacific jet. It is interesting to note the position of the subtropical ridge in the PNA- and ENSO-related patterns, as this is helpful in pattern identification: The ridge is over the Hawaiian Islands in the former but southeastward of Islands in the latter. The variability timescales of the patterns are also distinct: subseasonal and interannual, respectively (Figure 3). The separation of the PNA- and ENSO-related patterns is important as PNA was

once viewed as the extratropical response of ENSO. The PNA and NPO/WP patterns are also distinct, notwithstanding the broadly similar structure over the North Pacific–North American region; closer inspection reveals the two patterns to be in spatial quadrature in this sector; for example, the NPO/WP trough tracks the North American coastline, which is a nodal line in the PNA pattern.

Surface Temperature and Precipitation Impacts

Teleconnection patterns are of considerable interest because of their impact on surface hydroclimate. Significant climate anomalies on subseasonal-to-interannual timescales are often

attributable to a dominant phase of one or more teleconnection patterns. Figure 4 shows the SLP, surface temperature, and precipitation footprints of the NAO. The temperature and precipitation data sets used in this analysis are from the Climate Research Unit (CRU) of the University of East Anglia, namely the TS 3.1 climate database. The SLP pattern bears striking resemblance to the 200-hPa height pattern (Figure 2(a)), indicating an equivalent barotropic vertical structure. The strongest impacts of the NAO emerge over Europe and North Africa. The NAO results in nearly all of Europe experiencing above-normal temperatures, while cooler temperatures prevail from Saharan Africa east-northeastward to the eastern Mediterranean, Middle East, and the Arabian Peninsula. The temperature pattern at the surface results largely from advection of climatological temperature by the NAO circulation (i.e., $-V_{NAO} \cdot \text{Grad}(T_{CLIM})$); for example, cooler temperatures over Africa arise from the cold advection by

northeasterlies tracking the eastern flank of the high SLP cell. Correlation coefficients are shown in Figure 4 to indicate the significance of the impact, although they conceal the fact that temperature anomalies over Europe are larger than those over Africa. The precipitation pattern likewise shows a wet-dry dipole with northern Europe experiencing above-normal, and the Iberian Peninsula and southern Europe below-normal precipitation. This impact is not obvious from the geopotential and SLP patterns unless the impact of NAO on the jet stream, and thus storm tracks, is considered. In the depicted positive phase, NAO results in enhanced zonal wind north of the Azores center and reduced zonal wind to the south. The northward displaced jet stream and storm track account, in part, for the observed precipitation dipole.

The NAO influences the surface climate of North America as well. A north-south dipole in temperature is again observed: cold in northeastern North America, warm to the south; both

Figure 4 (a) Temperature, (b) precipitation, and (c) SLP footprints of the wintertime NAO pattern seen in Figure 2. Correlation between NAO principal component and CRU temperature and precipitation is contoured at 0.15 intervals; the zero contour is suppressed. For SLP the regression coefficient between the principal component and the SLP field from the CFSR is contoured at 1-hPa intervals, and the zero contour is suppressed. NAO, North Atlantic Oscillation; CFSR, Climate Forecast System Reanalysis.

consistent with the regional SLP signal. The precipitation impacts are less coherent and significant than in Europe, except along the west coast of the Labrador Sea and Davis Strait; the deficit here resulting from off-shore moisture advection by the NAO circulation. Interestingly, there is a significant dry anomaly on the central US West Coast that is associated with a weak ridge over the Gulf of Alaska ([Figure 2\(a\)](#)). This impact feature is revisited when annular modes are discussed.

The surface signatures of the ENSO-related pattern are shown in [Figure 5](#). The SLP signature is notably weak and focused in the Gulf of Alaska. Unlike NAO where regional thermal advection shaped surface temperature, the significant ENSO-related warming of the global northern Tropics (at both lower and upper levels) results from the propagation of atmospheric waves instigated by ENSO-related diabatic heating changes over the tropical Pacific. There is also a tendency for warmer winters across much of North America, centered on the United States–Canadian border, along with northern Europe and East Asia. Precipitation impacts are also notable in the

deep Tropics, with drying in eastern South America and increased precipitation over eastern Africa. The ENSO-related pattern results in a southward shift of precipitation across North America with increased precipitation along the US West Coast and southern tier states. Equally noteworthy are the positive precipitation anomalies over the northern Indian subcontinent, including the Himalayas. It is important to note that [Figure 5](#) does not fully capture the canonical ENSO impact on winter hydroclimate (e.g., as defined from correlations of the Niño 3.4 SST index) but comes close in most regions.

The NPO/WP pattern results in significant modulation of the North American surface climate ([Figure 6](#)). The SLP pattern is robust and oriented much as the NAO's, reflecting similar variability mechanisms. The NPO/WP circulation in the lower troposphere leads to impressive temperature correlations (exceeding 0.5) over central-eastern North America from anomalous thermal advection and related meteorological feedbacks; see Linkin and Nigam for more information. Intrusion of the sub-Arctic air into the continental interior in

Figure 5 Same as in [Figure 3](#) except for ENSO pattern (a) temperature, (b) precipitation, (c) sea-level pressure. ENSO, El Niño–Southern Oscillation.

Figure 6 Same as in [Figure 3](#) except for the WP/NPO pattern (a) temperature, (b) precipitation, (c) sea-level pressure. WP/NPO, West Pacific/North Pacific Oscillation.

the negative NPO/WP phase (weakened Aleutian Low) leads to below-normal temperatures, especially to the east of the Rockies, for example. The high correlations suggest that between one-quarter and one-half of the monthly temperature variance in the core influence region is explainable by NPO/WP variability. The precipitation impact is weaker and the spatial pattern less coherent, but potentially important in the Pacific Northwest and southern Great Plains. Like the NAO, the NPO results in meridional perturbation of the jet stream in its exit region; since this occurs over the wide Pacific Basin, the related storm track modification is not manifest in analysis of continental precipitation.

The PNA pattern's influence on North American surface hydroclimate ([Figure 7](#)) is, perhaps, most impressive. The SLP footprint in the Bering Sea and Gulf of Alaska is ~ 6 hPa, larger than of the other Pacific Basin patterns, including ENSO. The temperature impact is characterized by a strong northwest–southeast dipole across North America. Not surprisingly, the impact is focused on Northwest

Canada and the Southeast United States, the third and fourth centers of action of the pattern, respectively; again, with anomalous thermal advection defining the large-scale impact structure, if not its amplitude. At first glance, the precipitation impact appears similar to the opposite phase of the ENSO-related pattern ([Figure 5\(b\)](#)). Closer inspection, however, reveals a subtle shift in the greatest precipitation correlation regions. The PNA response is defined by large correlations over interior eastern North America, centered on the Tennessee and Ohio Valleys and extending across the Great Lakes into Northern Canada. A similarly signed signal is evident in the Pacific Northwest and Alaska as well. The positive-phase PNA precipitation response ([Figure 7\(b\)](#)) thus consists of only deficits across the United States. The deficit over the eastern United States results from the southward displacement of the Atlantic jet and storm track that are linked to the circulation anomalies associated with the third and fourth centers of the PNA height pattern.

Figure 7 Same as in [Figure 3](#), except for the PNA pattern (a) temperature, (b) precipitation, (c) sea-level pressure. PNA, Pacific–North America.

Stratospheric Signature

Teleconnection patterns are obtained from the analysis of connectivity of tropospheric climate variability. Understanding the mechanisms generating the remote response, i.e., teleconnectivity, in some cases warrants analysis of the related stratospheric links since stratospheric circulation can be an influence pathway between distant tropospheric regions. The enabling role of the stratosphere in generating aspects of tropospheric teleconnectivity is getting increasing attention in observational and modeling analyses. Two of the four tropospheric teleconnection patterns – NAO and NPO/WP – exhibit impressive stratospheric links ([Figure 8](#)). Not surprisingly, both involve meridional displacement of the subtropical jets, especially in the jet-exit sector. Such change in the tropospheric jet structure (a poleward shift in the positive NAO and NPO/WP phase) modulates the refractive index for the meridional-vertical propagation of planetary waves; a poleward jet shift, for instance, reduces the orographically forced stationary wave response in both the troposphere and stratosphere in dynamical models. Jet perturbations influence not only wave

propagation but also wave forcing; the latter by modulating flow over orography and regions of strong climatological vorticity gradients, for instance. The dynamical and thermodynamical mechanisms linking the troposphere and stratosphere are of great interest in modern climate studies.

[Figure 8](#) shows the regressions of the NAO and NPO/WP PCs on geopotential heights at 100 hPa (~16 km), 50 hPa (~20 km), and 10 hPa (~30 km); the NAO ones are in the left column. The NAO footprint in the stratosphere is significantly annular, i.e., anomalies of one sign in the polar region surrounded by opposite-signed anomalies in the midlatitudes. The tropospheric structure is less annular, prompting some to view NAO as the regional expression of the annular mode of SLP; the annular modes are discussed in a later section. The NAO stratospheric structure can be broadly characterized as consisting of out-of-phase variations of the polar vortex and surrounding regions. The NPO/WP one, on the other hand, reflects displacement of this vortex into North America. This difference between displacement of the vortex and the breakdown or splitting of the vortex is analogous to the two distinct

Figure 8 Stratospheric footprints of the two leading teleconnection patterns with substantial stratospheric signatures: (a)–(c) show the regression of the NAO PC onto 10-mb, 50-mb, and 100-mb normalized geopotential height anomalies, respectively. The contour interval is 0.2 standard deviations. The zero contour is suppressed in all cases. Panels (d)–(f) show the same except for the WP/NPO pattern. NAO, North Atlantic Oscillation; PC, principal component; WP/NPO, West Pacific/North Pacific Oscillation.

types of sudden warming events that occur in the stratosphere. In the case of a split vortex or complete breakdown of the vortex, an equivalent barotropic structure is observed as in the case of the NAO stratospheric signature. The NPO-related vortex displacement tends to be more baroclinic in nature, at least in the stratosphere, as evidenced by the westward tilt with height.

SST Anomalies

The teleconnections described above represent standing modes of atmospheric circulation variability on subseasonal-to-interannual timescales. As such, it is of interest to inquire

into the nature of related SST anomalies, which in the Pacific Basin can provide additional discrimination between the overlapping height variability patterns. Figure 9 shows the SST correlation of the four PCs. The NAO SST footprint reveals a characteristic tripole feature in the Atlantic Basin, with cooler temperatures underneath strengthened westerlies in the North Atlantic. SST anomalies associated with the NAO also appear in the extratropical Pacific that are only slightly weaker than in the Atlantic. It is noteworthy that NAO variability is not correlated with tropical Pacific SSTs, at least contemporaneously during Northern winter months. Herein lies a great dilemma that serves as the basis for a significant portion of contemporary

Figure 9 Correlation between the leading wintertime teleconnection patterns: (a) NAO, (b) ENSO related, (c) NPO/WP, (d) PNA, and SSA anomalies. Contour/shading interval is 0.1 m while the zero contour is suppressed. NAO, North Atlantic Oscillation; ENSO, El Niño-Southern Oscillation; NPO/WP, North Pacific Oscillation/West Pacific; PNA, Pacific-North America; SSA, sea surface temperature.

subseasonal-to-interannual climate research: ENSO, which is slowly varying and more predictable on seasonal timescales, explains relatively little hydroclimate variance in the Northern extratropics. The NAO, by contrast, explains more surface climate variance but is substantially less predictable.

Not surprisingly, the SST signature of the ENSO-related height pattern consists of large tropical correlations that resemble El Niño SSTs in the equatorial Pacific. Notable correlations are also present in the western Indian Ocean and the tropical and extratropical Atlantic. These include the well-documented ENSO links to warming of the adjacent basins, as well as capturing of more than just ENSO variability by this PC; including, possibly, the secular trend and multidecadal variability. The NPO/WP's SST correlations are not unlike NAO's Atlantic ones: a weak, tripolar, horseshoe-like structure in the extratropical basin; unlike NAO, however, it exhibits weak links with other basins.

The PNA SST correlations are broadly similar to the NPO's – an SST tongue extending from Japan into the midlatitude Pacific, surrounded by opposite-signed SSTs along the North American coast from the Aleutians to Baja Peninsula – but somewhat stronger, especially in the deep Tropics. A helpful distinction is the placement of the coastal anomalies: the off-coastal maximum in NPO/WP vis-à-vis the coastal maximum in PNA. The SST correlations of all three Pacific height patterns likely contain elements of the ENSO and Pacific decadal SST variability patterns, in view of the potential aliasing of SST variability due to the short analysis period (1979–2008) and the atmospheric-only nature of the PCA. An RPCA analysis of the combined variability of upper-tropospheric geopotential height and SST in a longer record minimizes such aliasing; see [Nigam \(2003\)](#) for more information.

The PNA SST correlations extend into the equatorial Pacific ([Figure 9\(d\)](#)), as noted above. This pattern was once thought to be the extratropical atmosphere's response to El Niño because of such correlations, despite the dominant intra-seasonal timescales of its PC (or teleconnection index) and the modest correlation ($0.3 \sim 0.4$) of the latter with the Niño 3.4 SST index. The potential aliasing of SST variability, noted above, led to PNA's spurious linkage with tropical SSTs: The PNA PC from the combined analysis of 200-hPa geopotential height and SST variations is correlated with the Niño 3.4 SST index at only 0.07.

The contemporaneous SST correlations of the recurrent 200-hPa height variability patterns raise the interesting question of cause and effect: Are the height patterns forced by the underlying SST patterns, or vice versa? The answer to this question is, unfortunately, complex as it is dependent on both the basin region and the variability pattern. Generally speaking, SST variations in the deep Tropics (e.g., ENSO related) are influential on the atmosphere on monthly timescales whereas variations in the middle–high latitude basins are the response. Consider the NAO: In the displayed phase (positive), the SLP pattern ([Figure 4\(c\)](#)) strengthens both the Icelandic Low and Azores High along with a northward displacement of the jet stream and storm track. This will result in anomalous westerly wind stress on the ocean northward of the climatological jet position, leading to increased vertical mixing and latent heat flux, and thus cooling of the surface

layer. The opposite arguments apply in the region off the US coast, where SSTs are warmer. The strengthened Azores High is, likewise, associated with stronger trade winds in the tropical Atlantic, leading to more upwelling and mixing off the African coast, and thus colder SSTs. As noted earlier, the influence direction is dependent on the basin region and variability timescales. The extratropical oceans can be influential on longer timescales and even on subseasonal ones through their preconditioning role. Clearly, this is an active research area in climate science requiring the use of advanced modeling techniques.

Northern Summer Teleconnections from RPCA

The Northern summer stationary waves are considerably weaker than the winter ones because of the weaker and northward displaced jet (and storm track). The summer regime thus consists of monsoonal circulations and only modest stationary Rossby wave propagation. For these reasons, the winter anomalies have been the target of most teleconnection analyses. The structure of recurrent height variability in Northern summer is however still of interest. A rotated EOF analysis (RPCA) of June, July, and August (JJA) 200-hPa geopotential height anomalies is conducted in a fashion similar to the wintertime analysis except for the analysis domain. The domain used in the summer analysis is restricted to $20\text{--}90^\circ\text{N}$. This change is made to emphasize the extratropical modes; inclusion of the Tropics leads to a noisier analysis.

The summer results are displayed in [Figure 10](#). The leading patterns are, perhaps, relatable to the winter patterns. The first one is labeled NPO/WP due to the presence of a north–south dipole over the North Pacific near the date-line. The second one is referred as the NAO on account of the dipole over the northeastern Atlantic. An ENSO-related pattern or a PNA look-alike was not identified. The third leading pattern exhibits higher geopotential heights in the global Tropics and a coherent ridge over the western sub-Arctic. The first four modes explain less variance than in winter, indicating the more disorganized structure of summertime variability. Notice that even the patterns resembling NPO/WP and NAO are more regionally confined, consistent with brief remarks on reduced Rossby wave activity in Northern summer; see [Folland et al. \(2009\)](#) for more discussion of the summer NAO, the most studied summer teleconnection.

Southern Winter Teleconnections from RPCA

The very different distribution of continents and mountains in the Southern Hemisphere (SH) results in muted seasonality and stationary waves. The SH winter climatology is dominated by a strong polar vortex, and thus more zonally symmetric flow. The lack of continents and large mountain ranges lead to reduced orographic forcing and land–sea contrast, both resulting in diminished stationary Rossby wave activity. An RPCA analysis of the SH winter height variability is briefly discussed here. It is identical to the Northern winter

Figure 10 Four leading summertime (JJA) teleconnection patterns that emerge from a rotated EOF analysis of 200-mb geopotential height. The domain of the analysis is 20–90° N. Only the leading two modes, (a) and (b), are clearly identifiable as the NPO/WP and NAO, respectively. Contour/shading interval is 8 m; the zero contour is suppressed. Percentage of explained variance: (a) 11.9, (b) 8.5, (c) 8.0, (d) 7.4. JJA, June, July, August; EOF, empirical orthogonal function; NPO/WP, North Pacific Oscillation/West Pacific; NAO, North Atlantic Oscillation.

analysis: the domain includes the Tropics (30° N–90° S), and the eight leading patterns are rotated using the varimax criterion.

The four leading patterns are shown in [Figure 11](#). The first one is analogous to the NAO, but slightly more annular in nature. The larger amount of explained variance (~16.4%) relative to the other patterns indicates that SH variability is dominated by fluctuations of the polar vortex; not surprising, given the zonal nature of the SH circulation. Patterns 3–4 are more classic teleconnections: The third pattern consists of a strong center in the Bellingshausen Sea in the far South Pacific, surrounded by three weaker centers, while the fourth one is dominated by a wave-3 pattern around the pole. Patterns 1, 3, and 4 were identified in some form by [Mo and White \(1985\)](#), the first analysis of SH

winter variability; see this study for more details on SH teleconnections.

For reference, [Figures 12–14](#) show the surface temperature and precipitation footprints of select winter patterns of SH height variability; in the interest of space, only a few prominent features are noted below. Because of its polar domain, the first pattern has weak temperature and precipitation footprint over the inhabited continents. Pattern 2 ([Figure 12](#)) is linked with wide-spread warming of the Tropics, and more precipitation over Amazonia and southern South Africa, and a precipitation dipole over Australia (dry to the east, wet in the north); some of these signals are well documented in the literature as El Niño's SH winter impact. Pattern 3's precipitation impact is weak but it is linked to a prominent north–south temperature dipole over South America ([Figure 13](#)).

Figure 11 The leading patterns that emerge from a rotated EOF analysis of 200-mb height in SH wintertime (JJA). The domain used is 30° N–90° S. The contour interval is 10 m while the zero contour is suppressed. Panels (a)–(d) represent patterns 1–4. Percentage of explained variance: (a) 16.4, (b) 11.9, (c) 11.5, (d) 10.4. JJA, June, July, August; EOF, empirical orthogonal function; SH, Southern Hemisphere.

Although not expected from the height anomaly structure, mode 4 exerts substantial impact over Australia (Figure 14), with wet anomalies everywhere except the southeastern region.

Annular Modes

Closely related to teleconnections are the annular modes, which have received considerable attention in recent years. While teleconnections are the climate links between geographically separated regions, the annular modes represent the seesaw (i.e., out-of-phase links) between the poles and the surrounding midlatitudes; annular modes can be viewed as the teleconnections of the polar region. The annular mode in the NH and SH is referred as the Arctic Oscillation and

Antarctic Oscillation (AO and AAO), respectively. The annular pattern is obtained from EOF analysis of the monthly 1000-hPa geopotential height anomalies (700 hPa for SH) poleward of 20° for the entire year. Key differences from the previous RPCA analysis are the lack of rotation of the PCs and the search for recurrent patterns among all calendar month (and not just winter) anomalies. Note, unrotated analyses often generate more spatially extended patterns in order to maximize the explanation of variance, as seen in Figure 15, which also shows the temperature and precipitation impacts of the annular patterns. Note, ‘annular pattern’ rather than ‘annular mode’ is, perhaps, more reasonable terminology as only spatial (and not spatiotemporal) variability is analyzed for their extraction.

The annular modes bear close resemblance to the leading mode extracted from RPCA of 200-hPa heights in each

Figure 12 Same as in [Figure 3](#), except for the SH pattern 2. This is likely related to ENSO. ENSO, El Niño-Southern Oscillation; SH, Southern Hemisphere.

hemisphere. The AO has a stronger, coherent center of action in the Aleutians in addition to the essential elements of the NAO pattern. Not surprisingly, AO's year-round temperature and precipitation impacts are very similar to the winter impacts of the NAO (cf [Figure 4](#)). The close similarity of AO and NAO has led many to question whether the NAO is merely a region manifestation of the larger-scale annular mode (AO). It is noteworthy that neither the AO nor AAO are

strikingly annular; especially the AO. The AO footprint in the lower stratosphere (not shown) however appears substantially more annular; as does the NAO footprint (cf [Figure 8\(c\)](#)).

Subseasonal Tropical Variability – MJO

The ENSO-related pattern reveals one way in which the Tropics can influence the extratropics: An interannual shift in the preferred area of tropical convection/precipitation leads to anomalous divergent motions, which generate a Rossby wave source that, in turn, alters midlatitude storm tracks and extratropical climate. Zonal variations in tropical convection occur on timescales other than interannual ones as well: The MJO – representing convection variability in the tropical Indian Ocean and Western Pacific basins on 30- to 50-day timescales – can, like ENSO, influence the climate in the extratropics, albeit on subseasonal timescales.

When the MJO is active, convection is enhanced over the eastern Indian Ocean at the expense of the West Pacific. This generates an anomalous divergent circulation that leads to retraction of the East Asian jet. The jet retraction and related modulation of storm tracks influence the circulation and hydroclimate over the North Pacific and North American regions; for example, weaker Aleutian Low and higher than normal heights over eastern North America. These MJO influences can implicitly influence the NAO and PNA structure, but only modestly as these teleconnection patterns are robustly manifest in the MJO-filtered data as well.

Figure 13 Similar to [Figure 12](#), except only showing the South American temperature footprint for pattern 3.

Figure 14 Similar to [Figure 12](#), except the temperature (a) and precipitation (b) footprints are shown only over Australia for pattern 4.

Subseasonal Teleconnection Analysis

Climate teleconnections, discussed above, were obtained from the analysis of monthly averaged anomalies, using techniques keyed to an optimal accounting of the temporal variance. These attributes steered the analysis toward extraction of the mature phase of the leading teleconnection patterns. Monthly averaging filtered the large-scale synoptic waves in the troposphere and facilitated focus on the ‘standing’ component of low-frequency variability. A month is not too long a period in context of large-scale ocean–atmosphere interaction, but it is an extended averaging period in context of the dynamical and thermodynamical processes generating climate teleconnections. These processes evolve rapidly – on pentad-to-weekly timescales – and their resolution is critical for the description of the nascent-to-mature and decay phases of the teleconnection patterns, and for advancing understanding of the excitation mechanisms. Insights into the evolution of teleconnection

patterns can advance the subseasonal prediction of the climate system.

In the following, the submonthly evolution of PNA variability is briefly discussed to illustrate an interesting line of contemporary teleconnection research. The PNA pattern is chosen as its evolution was described earlier from a simpler (and less accurate) analysis ([Nigam, 2003](#)), facilitating assessment of the new analysis strategy. The CFSR, used earlier at monthly resolution, is analyzed at pentad (5-day average) resolution in this section. The analysis period covers 30 extended winter (November–March) seasons from 1979 to 2008, and the 200-hPa geopotential height anomalies are analyzed, as before. To emphasize pattern development and decay, a technique called *extended* EOF analysis is used. Extended EOF analysis is a powerful spatiotemporal analysis technique, but one that can be easily implemented using the standard EOF analysis infrastructure; by substituting a contiguous *series* (e.g., from $T - 2$ to $T + 2$ time steps) of anomaly patterns in place of the contemporaneous one (i.e., $T = 0$). The leading variability mode in this case is not a single spatial pattern but the most recurrent temporal series of spatial patterns, or the most recurrent spatiotemporal pattern. In this illustrative example, a 5-pentad window is chosen ($T - 2$ to $T + 2$ pentads). The seven leading modes are rotated using the varimax criterion to allow for more spatial discrimination.

The leading mode from this spatiotemporal analysis represents the development and decay of the NAO (not shown). The fourth leading mode is closely related to the PNA; a 5-pentad evolution is shown in [Figure 16](#). An interesting finding here is that the development and decay of the PNA is associated with westward progression of height anomalies across the high latitudes. At $T = -3$, there is a notable height center in the NAO region of the North Atlantic. It is thus not surprising that there is a small but significant lag correlation between modes one and four ($r = -0.35$), with the negative NAO *leading* the positive-phase PNA pattern. The retrogression of the northern height anomalies is consistent with the advection of planetary vorticity, but cannot adequately explain the development of the robust anomaly center south of the Aleutians.

To help set forth a plausible basis for the NAO–PNA link, the impact of the NAO on the meridional wind is assessed; meridional winds highlight the shorter zonal scales of the midlatitude quasi-geostrophic flow, and thus the zonal propagation of stationary Rossby waves. [Figure 17\(a\)](#) shows contemporaneous regressions of the PC associated with the positive NAO pattern onto the 200-hPa meridional wind, along with the climatological winter position of the East Asian jet. The NAO apparently forces a wave pattern in the subtropics between East Africa and southern Asia that culminates in the North Pacific. [Figure 17\(b\)](#) shows the 2-pentad lag regression of the same NAO PC onto the 200-hPa zonal winds. The result is a subtle retraction of the East Asian jet, consistent with the negative-phase PNA pattern.

The analysis presented above serves to illustrate the nature of contemporary research in climate teleconnections rather than definitive findings on PNA evolution; durable and corroborated findings on teleconnection evolution have yet to

Figure 15 The two annular modes, (a) the Arctic Oscillation and (b) the Antarctic Oscillation (AAO), are shown along with their temperature and precipitation footprints. Annular modes are calculated as the leading EOF of 1000-mb geopotential height (700-mb geopotential height for AAO). Note that the entire year is used to calculate the pattern. Contour interval for the height patterns is 5 m. Hydroclimate footprints are shown as correlations between the principal components and CRU temperature and precipitation, contoured at 0.15 intervals. For all panels, the zero contour is suppressed. EOF, empirical orthogonal function.

Figure 16 The fourth leading mode from a rotated, extended EOF analysis on extended winter 200-hPa height at pentad resolution. This mode closely resembles the PNA. The figure is presented as the lead/lag regression ($T = -4$ to $T = 0$) of the PC onto the height field. The contour interval is 10 m and the zero contour is suppressed. EOF, empirical orthogonal function; PNA, Pacific–North America; PC, principal component.

Figure 17 (a) The contemporaneous regression of the leading PC (NAO) onto 200-hPa meridional wind is contoured/shaded at 0.5 m s^{-1} intervals. The zero contour is suppressed. Bold red contours show the winter climatology of the 200-hPa zonal wind at 10 m s^{-1} intervals. (b) The 2-pentad lag regression of the leading PC (NAO) onto the 200-hPa zonal wind field is contoured/shaded at 1 m s^{-1} intervals with the zero contour suppressed. As in (a), bold red contours represent the winter jet climatology. NAO, North Atlantic Oscillation; PC, principal component.

emerge. The recent focus on submonthly climate prediction has however spurred climate scientists to investigate the development and decay of the leading winter teleconnection patterns.

Synopsis

Surface temperatures have risen by about 0.6 °C during the twentieth century. This article addresses the quality of the basic temperature data over the terrestrial and marine domains. The warming during the century has not occurred in a linear fashion but in two periods, from about 1920 to 1945 and since about 1975. Spatial patterns of the change over the twentieth century indicate many regions showing statistically significant warming, but not all. Changes in temperature are also assessed in greater detail: showing that the warming is occurring more by reductions in cold extremes compared to increases in warm extremes and occurring more at night than during the daytime. The twentieth century warming is finally placed in a longer context by considering millennial-length paleoclimatic information from many diverse proxies. The latest evidence shows that the twentieth century has been both the warmest of the millennium and the warming rate during it has been unprecedented. The 1990s (1991–2000) was the warmest decade of the twentieth century and 1998 the warmest year. The first decade of the twenty-first century (2001–10) was warmer again, 0.20 °C above the 1990s, with 2010 almost as warm as 1998. The 10 warmest years are all the years from 2001 to 2010, but with 2008 replaced by 1998.

Quality of Temperature Data

Any assessment of trends or changes in temperature requires that all the observations have been taken in a consistent manner. Climatologists refer to this property as homogeneity. Time series of temperature are homogeneous if the variations exhibited are due solely to the vagaries of the weather and climate. Numerous nonclimatic factors influence the basic data. Without some form of adjustment, erroneous conclusions can be drawn regarding the course of 'true' temperature change. The factors vary depending upon the data source and are briefly considered in the next two subsections for the terrestrial and marine components of the Earth's surface.

Land

It is extremely rare if observational protocols and the environment around an observing location have remained exactly the same during the station's history. Changes are likely to have occurred with the instruments, their exposure and measurement techniques, in the location of stations and the height of the instruments, in the number and times of observations per day, and the methods used to calculate daily and monthly

averages. The two most important factors with respect to long-term consistency are changes brought about by the introduction of Stevenson screens and changes in the environment around some of the stations across the world. Both factors are difficult to deal with using conventional approaches of station homogeneity assessment, as neighboring sites are all likely to be similarly affected.

The commonly used louvered screen developed by Stevenson in the 1870s is now the standard around the world, although different countries use variants of a similar design. Prior to this, most thermometers were positioned on poleward-facing walls (i.e., out of direct sunlight), but this poses problems in high-latitude regions in the summer. The issue of the different exposures before screens has recently begun to be addressed by rebuilding the early exposures (using nineteenth century information) and taking modern parallel observations. Comparison of these measurements confirms expectations and indicates that prescreen temperatures are about 0.5 °C too warm during the summer months from May to September. Winter temperatures are barely affected by the change. Only the longest series are affected, but countries or regions that introduced screens later (e.g., Australia in the 1910s) have yet to fully allow for the effects in the prescreen parts of their series.

The second factor is that the location may have been a small town in the nineteenth century, but now could be a city of several million. Development around the site (urbanization) leads to relative warming of city sites compared to, still rural, neighbors. On certain days, particularly with anticyclonic weather, cities can be warmer than rural surroundings by up to 10 °C. For monthly averages, this reduces to up to 2 °C, more so for inland continental, compared to coastal, locations. Cities that have grown rapidly over the twentieth century tend to be more affected, compared to European locations where development has taken place over many centuries. Assessment of the urbanization influence suggests that the overall influence (at hemispheric scales) is small (up to 0.02 °C per decade).

Additional factors influencing homogeneity are that most stations have moved at least once during their lifetime. Also, of importance is the time observations that are made each day. Even today, there is no accepted standard, and countries are allowed to choose whatever times suit them. English-speaking countries have tended to use the average of the daily maximum and minimum readings each day to measure daily and monthly averages. Some countries have switched to this method mainly because of its ease, while others retain their national standards (averages of measurements made at fixed hours, between 3 and 24 times per day). Changes to sites or to the methods used to calculate monthly averages influence the time series, often in an abrupt manner (temperatures changing to a new level by up to 2 °C in extreme cases). Ideally, when new sites or observation protocols are adopted, parallel measurements are recommended, enabling corrections to be calculated. These corrections are referred to as homogeneity adjustments. Sadly, although clearly recognized as being necessary, few countries carry out sufficient overlapping measurements. The most common problems relate to location moves, particularly to airports in the 1940s and 1950s.

Recently, many countries have switched from mercury-in-glass thermometers to electrical resistance thermistors, to reduce manpower, automating measurements. The sum total of all these problems can be disentangled, if adequate station history information is available, but it is generally a tedious process locating all the necessary information. In some countries, it is just not available in sufficient detail. Site moves and changes to observation protocols are less important than the widespread changes to screens and changes in the environment around a station as the effects can be of both signs and occur at irregular points in time. The overall effect on large-scale averages is only important if many sites are affected by changes occurring at the same time (such as the introduction of screens and urbanization issues). Homogeneity adjustments are necessary and vital for local scales, but are relatively unimportant at the hemispheric and global scales.

Several groups in the UK, USA, Russia, and Japan have extensively analyzed the basic surface temperature data (between two and seven thousand stations), adjusting the data for the abrupt changes and removing urban-affected stations, and have reached similar conclusions about the course of temperature change over the instrumental period since 1850. It is highly unlikely that every problem has been corrected for, but the different techniques used, give confidence that large-scale changes over the last 160 years are both real and well-documented. The agreement on large-scale trends with marine

and lower tropospheric temperature estimates (see later discussion of satellite records) confirms this confidence.

Marine

Terrestrial parts of the world constitute only 30% of the Earth's surface, so for a global picture it is vital to include the oceans. Historical temperature data over marine regions are largely derived from *in situ* measurements of sea surface temperature (SST) and marine air temperature (MAT) taken by ships and buoys. To be of use, each measurement must be associated with a location. Up to 15% of marine data are thought to be mislocated (ships located on the land!) and these values must be discarded. It is obviously harder to reject data still located over the ocean, but all analyses of the raw data also attempt to remove or correct these problems. Plotting ship tracks has helped to considerably reduce the numbers of mislocated reports.

Marine data are also beset with homogeneity problems, but they are distinctly different from the terrestrial realm. For MAT data, the average height of ships' decks above the ocean has increased during the twentieth century, but more importantly, daytime measurements are influenced by the solar heating of the ship, restricting use, at present, to only the nighttime MAT (NMAT). For SST data, the changes in sampling method from uninsulated canvas buckets (generally prior to the early 1940s) to engine intake measurements (early 1940s onward) cause an artificial rise in SST values of 0.3–0.7 °C. Recently, the greater preponderance of buoy (as opposed to ship) SST data has led to a further need for adjustments. Data from buoys were rapidly used when they became available, as coverage was dramatically improved. Now with over 20 years of overlap in measurements it is becoming apparent that the absolute temperatures from buoys are slightly cooler (0.1–0.2 °C) than those taken by ships. Estimates of SST from satellites are also beginning to be widely used, but these can be offset from *in situ* measurements by several degrees.

In the combination of marine data with land-based surface temperatures, SST data are preferred to NMAT, because they are generally more reliable, principally, as there are at least twice as many observations, daytime MAT values having been contaminated by the ships' infrastructure. Additionally, the much stronger day-to-day correlation of SST compared to MAT means that averages of a few SST values are much more reliable than comparable averages of MAT data. Absolute values of SST and land air temperatures may differ by up to 10 °C near some coastlines, so the two cannot be directly combined. Instead, anomalies are used (departures or differences from average) assuming that anomalies of SST and MAT agree on climatological (monthly and greater) timescales. Correction of the SST data for the change from canvas buckets is achieved using a physical-empirical model to estimate the degree of seawater cooling that occurs in buckets of varying designs. The cooling depends on the ambient weather conditions, but this can be approximated by climatological averages. Corrections are greatest in regions with the largest air-sea temperature differences (i.e., winters compared to summers) and the technique minimizes residual seasonal cycles in pre-World War II (pre-WWII) SST values compared to post-1945 values.

Since both the marine and the land components are independent, the two records can be used to assess each other after they have been separately corrected. The components have been shown to agree with several groups on both hemispheric scales using island and coastal data.

Aggregation of the Basic Data

Both the land and the marine data are irregularly located over the Earth's surface. To overcome the greater density of data in some regions, it is necessary to interpolate the data generally to some form of regular latitude/longitude grid.

Land

Differing station elevations and national practices with regard to the calculation of monthly mean temperatures means that interpolation to a regular grid is much more easily achieved by converting all the monthly data to anomalies from a common reference period (often referred to as a climatology). The period with best available data is 1961–90. The simplest interpolation scheme is the average of all stations that are located within each $5 \times 5^\circ$ grid box. More complex interpolation methods yield essentially the same results on all spatial scales. A potential drawback of gridding schemes is that the variance of grid box time series is affected by changing numbers of stations within each grid box through time, although it is possible to allow for this.

Marine

For SST, the aggregation is approached in a somewhat different manner. The changing location of each observation means that it is necessary, by interpolation, to derive the 1961–90 climatology for each 1×1 square of the world's oceans for each 5-day period (pentad). SST anomaly values with respect to this climatology are then averaged together for each month for each 5×5 grid box, the same as used for the land component.

Combination into One Dataset

Combination of the two components occurs in the simplest manner. Anomaly values are taken from each component. They are combined using weights determined by the errors of estimates of the land and the marine part. Around coastal areas this gives greater weight to the marine part.

Hemispherical Global Time Series

With the basic data now in 5° latitude/longitude grid boxes, calculation of large-scale averages is relatively simple but must take into account the different sizes of grid boxes in tropical, compared to polar, latitudes. This is simply achieved by weighting each grid box by the cosine of its central latitude value.

Figure 1 shows annual hemispheric and global time series for the 1850–2010 period using the HadCRUT3 dataset. The series derived by the other groups are very similar. Table 1

gives monthly linear trend values, estimated by least squares, for the three domains calculated over the 161-year period and for some other subperiods (1901–2010, 1920–44, and 1975–2010). For the 1901–2010 period, global average surface temperature has risen by 0.83°C , a value that is statistically significant at the 99.9% level. All the monthly values also exhibit a significant warming. The choice of periods such as 1925–44 and since 1975 is determined by looking at Figure 1, so an element of subjectivity could have influenced the choice. Analysis of all possible periods longer than 10 years has been considered in one study. Since 1945, all periods longer than 22 years indicate warming but are only statistically significant for periods ending after about 1990. There is also a segment of significant warming for periods ending in the mid-1940s. All periods longer than 82 years all produce positive trends.

While both hemispheres show similar degrees of warming, it is also apparent that many warm and cool years, relative to the underlying trend, are in common. Many anomalous warm years are coincident because they relate to El Niño years in the eastern equatorial Pacific. El Niño events cause somewhat predictable patterns of temperature and precipitation patterns over the world, with more regions experiencing warmer than cooler conditions. The opposite phase of an El Niño is termed a La Niña event. Anomalous patterns of temperature and precipitation also occur here, which to a first order are opposite to those during an El Niño event. Polar regions and much of northern Eurasia are largely unaffected by such an influence. A commonly used measure of the El Niño or La Niña state of the atmosphere is the normalized pressure difference between Tahiti and Darwin, Australia (referred to as the Southern Oscillation index (SOI)). Figure 2 is a scatter plot of the residual annual global temperature averages (the difference between each annual value and the smoothed curve) and the SOI for the 12-month average from July of the previous year through to June of the present year. The SOI explains about 30% of the variance of these residual temperatures. This analysis indicates that the next warm year will likely occur when the next El Niño occurs.

A few cool years can be related to the climatic effects of explosive volcanic eruptions, which are large enough to put considerable amounts of dust into the stratosphere. Once there, the dust forms a veil over the Earth, reducing solar radiation and cooling the surface, particularly land areas. Surface cooling of about $0.2\text{--}0.3^\circ\text{C}$ followed the eruption of Mt Pinatubo in the Philippines in June 1991, mainly in the northern summer months of 1992 and 1993. Volcanic eruptions, which only affect the troposphere (e.g., Mt St Helens in 1980), have little climatic effect as their ejecta are quickly dispersed by rain-making processes. The next major explosive volcanic eruption in the tropics is likely to cool global temperatures for 2–3 years following the eruption.

Accuracy of the Hemispheric and Global Series

The series in Figure 1 are subject to three sources of error: reductions in coverage earlier in the record; errors associated with the necessary bias adjustments in the basic data (discussed earlier for marine and land data, principally the switch to engine intake measurements in the early 1940s over the oceans

Figure 1 Hemispheric and global temperature averages on the annual timescale (1850–2010 relative to 1961–90). The smooth curves highlight variations on 20-year timescales.

Figure 2 The inverse relationship between the SOI and the residual global temperature (annual value minus the smoother curve seen in [Figure 1](#)). The SOI is the normalized sea level pressure difference between Tahiti and Darwin. Residual temperatures are for the calendar year, while the SOI is the average of July of the previous year to June of the current year. Also shown is the regression line (based on annual values for the years 1867–2010) and the correlation between the two series. The regression line slope of ~ -0.8 means that a change of one SOI unit affects global temperature by $\sim 0.08^\circ\text{C}$. Very strong El Niño events can be up to 0.16°C warmer and very strong La Niña years up to 0.16°C cooler.

and the introduction of screens in the nineteenth century and effects of urbanization around some sites for the land); and homogeneity adjustments to land records for site and procedural changes. These are all taken into account in the error estimates and annual hemispheric averages are accurate to within $\pm 0.05^\circ\text{C}$ (one standard error). Errors in the mid-nineteenth century were roughly twice modern values.

Analyses of the Temperature Record

The surface record has been extensively analyzed, principally over the past 35 years. The series in [Figure 1](#) has become one of the foremost series in major international reviews of the climate change issue, most recently by the Intergovernmental Panel on Climate Change (IPCC). Here several diverse aspects of the record are analyzed:

- trends in areas affected by monthly extremes;
- trends in maximum and minimum temperatures;
- daily extremes of temperature in two long European series; and
- the last 150 years in the context of the last 1000 years.

[Figure 1](#) clearly shows recent warming since the late 1970s. Five different groups monitor surface temperatures and all show similar courses of change over the last 160 years and similar rates of change to those given in [Table 1](#). Completely independent estimates of temperature change have been developed for the lower part of the troposphere, first from weather balloons (called radiosondes) from the 1940s and more recently by satellite estimates from microwave sounding units aboard polar-orbiting satellites (since the late 1970s). [Figure 3](#) shows a comparison at the global scale, of the two principal groups who collate the satellite data, for the period from 1979 to 2010. The surface temperature indicates a warming of 0.16°C per decade, in exact agreement with one of the satellite records. The difference between the two satellite records relates to the adjustments to their records that must be applied to derive a consistent record over the 32 years. [Figure 3](#) also illustrates the influence of the SOI on global temperatures with the major El Niño event of 1997/1998 and the slightly lesser ones during the 1980s and during 2009/2010. Variability from month to month is markedly greater for the lower troposphere than at the surface, particularly during the larger El Niño and La Niña events.

Figure 3 Comparison of monthly surface and lower tropospheric temperatures for the period 1979–2010. All series have been re-zeroed to the period 1979–2009. The trends given are based on all the years shown from 1979 to 2010.

Trends in Areas Affected by Monthly Extremes

The various groups that produce global and hemispheric temperature series also produce spatial temperature maps showing regions that were cooler or warmer than the 1961–90 base period. Similarly, it is possible to produce maps of temperature trends over specified periods. Interpreting these maps is often difficult as they tend to be dominated by the local level of variability. For example, the largest anomalies for a given month or year tend to occur in polar regions. Warming in Siberia may be large, but it is barely significant because of the large year-to-year variability. Trends in some tropical oceanic areas indicate highly statistically significant warming, but it may only be about 0.3–0.7 °C. To enable easier intercomparison of trends and extremes, from a local impact point of view, removing the effects of year-to-year variability highlights where significant changes are occurring. An appropriate transformation is the gamma distribution. Each grid box time series, on a monthly basis, is transformed from one in anomalies with respect to 1961–90 to percentiles based on the same period. Percentiles can be easily related to return periods (e.g., the 5th/95th percentiles are equivalent to the one in the 20-year return period). Using a normal distribution (i.e., simply dividing the grid box anomaly series by the standard deviation calculated over the 1961–90 period) works almost as well as the gamma distribution, but the latter is better in many regions of the world as monthly temperatures are often significantly negatively skewed.

Figure 4 compares the anomaly and percentile method for displaying annual temperatures for 2010. The zero anomaly and the 50th percentile contour are essentially the same in both plots. The percentile map, however, indicates extremely warm annual temperatures over many tropical and oceanic regions that might not warrant a second glance in anomaly form. 2010 shows 34% of the world's surface with data above the 90th percentile and 3% below the 10th percentile. How unusual is this, compared to other years? Figure 5 shows the percentage of the world's surface with data with temperatures greater than the 90th percentile (in red) and less than the 10th percentile (in blue) since 1900. An increase in the percentage of the analyzed area with warm extremes is evident (the largest area being 35%

in the warmest year (1998)), but by far the greatest change is a reduction in the percentage of the analyzed area with cold extremes. Some caution should be exercised while interpreting these results because of the large changes in coverage, particularly before 1951. The implicit assumption being made is that the average of the unsampled regions is the same as the average of the sampled regions. Coverage changes since 1951 are minimal, though, and even analyzing only those regions with data for the 1900–20 period produces similar series to those seen in Figure 5. The implications of these series are that before the mid-1970s most of the warming in this century was more apparent through less cold annual averages than excessively warm ones. Over the last 35 years, regions experiencing very warm annual anomalies have begun to increase dramatically.

Trends in Maximum and Minimum Temperatures

Up to now, all the surface temperature analyses have been based on monthly mean temperatures. This situation has arisen due to the widespread availability of this variable. As mentioned earlier, English-speaking countries have tended to measure daily and monthly means using maximum and minimum temperatures. Recently, extensive datasets of monthly mean maximum and minimum temperatures have become available since the 1950s. These enable recent warming patterns to be assessed for both day (maximum) and night (minimum) temperatures. The difference between day and night (the diurnal temperature range (DTR)) should prove a useful variable when considering what the causes of changes might be due to.

Homogeneity of the series poses more severe problems than for mean temperatures, as the various factors discussed earlier generally cause differential effects in the maximum and minimum series and station history information is even more important to decide upon adjustments. Analyses are restricted to the period 1950–2004 because of data availability issues in many regions of the world. Combining all available land regions, 'global' minimum averages warmed by 1.12 °C over the 55 years, while maximums warmed by only 0.78 °C. The DTR decreased by 0.34 °C. Most of the differences in warming rates occurred over the period from 1950 to about 1980. Over the last 25 years, trends have been similar in the two series.

Figure 4 Surface temperatures for 2010, relative to the 1961–90 average (a) as anomalies and (b) as percentiles. The percentiles were defined by fitting gamma distributions to the 1961–90 annual deviations relative to the 1961–90 base period for all 5×5 grid boxes with at least 21 years of annual data in this period.

Urbanization influences have been shown to have the same signature (warmer nights compared to days), so these studies have restricted analyses to nonurban stations. In most regions, however, these differential trends can be clearly related to increases in cloudiness which will raise nighttime, compared to daytime, temperatures. Longer records, back to the turn of the twentieth century, are available in a few limited regions. Analyses over the USA and southern Canada, for example,

show little change over the first half of the twentieth century, so the drop in DTR over the period 1950–80 is the main feature of the record.

Daily Temperature Extremes in Long European Series

The last two sections have considered extremes on a monthly basis, but public perception of climate change is often

Figure 5 Percentage of the monitored area of the globe having monthly surface temperatures above the 90th percentile (in red) and below the 10th percentile (in blue). Annual averages from these separate monthly analyses were averaged to get the annual values. The percentiles were defined by fitting gamma distributions to each month based on the 1961–90 period, using all 5×5 boxes with at least 21 years of data. The smooth curves highlight variations on decadal timescales.

influenced by daily extremes or runs of warm/cold days (e.g., heat waves or cold surges). In the context of the global warming issue, daily data are relatively unimportant as detection and attribution of human influences are primarily concerned with underlying trends on decadal timescales. In the public and political worlds though, changing frequencies of daily extremes are that how much of the global warming debate is perceived.

Daily temperature series present even greater problems for climatologists with respect to homogeneity than monthly data. Site and observation time changes are particularly important and in some cases it may not be possible to fully correct for all the problems. Few long daily temperature series, therefore, are totally homogeneous. Furthermore, the availability of long series in some parts of the world is often restricted to the last 50 years because earlier data have not been digitized (particularly in some developing countries of the world). Changes in the frequency of extremes may be occurring, but without long series it is difficult to judge whether recent changes are really unprecedented. In Europe, however, several 200+ year series have recently been developed which will be ideal for analysis.

The public perception of extremes is clearly cold winter and hot summer days, but in different regions it is necessary to define somewhat arbitrarily what is meant by cold and hot.

A cold day threshold of 0°C clearly has important consequences but what is hot in northern Europe clearly differs from what would be regarded as hot in southern Europe. Also, considering only absolute extremes ignores changes that might be taking place in the transition seasons. A better and universally applicable means of defining extremes is to let the data define the thresholds and to allow these to change from place to place and during the year. A number of groups over the recent decade have developed different sets of indices of extremes. These have recently been combined into a large set by the Expert Team on Climate Change, Detection and Indices (ETCCDI, <http://www.clivar.org/organization/etccdi/etccdi.php>). Here, a relatively simple example is presented, which is applied to three long European series.

The first step is an analysis to define the annual cycle of temperature on a daily basis, based on a common period such as 1961–90. Some smoothing of this cycle is necessary as 30 years is a relatively short period for definition. 1961–90 is chosen for compatibility with the other analyses in this section. Variability of a single day's temperatures from the annual cycle shows greater variability in Europe during winter compared to summer. Also most station data series throughout the year, but particularly in winter, tend to be negatively skewed, so

a normal distribution would be inappropriate as this would give a bias to the cold day count. Instead, it is necessary to fit a gamma distribution to the daily anomalies for each day of the year, again using the thirty 1961–90 days for each day. Now it is a simple matter to count the number of days above the 90th/95th (warm/very warm) and below the 10th/5th (cold/very cold) percentiles in a calendar year or in a season.

Figure 6 shows counts of warm/cold days for two of the long European series (Central England and Stockholm). Although there are differences between the stations in the timings of change, the overall picture is of an increase in warm days in the second half of the twentieth century, but the largest trend is a reduction in the number of cold days. Recent increases in warm days at the sites with longer records have only just exceeded similar counts in some decades of the eighteenth century. Cold day counts, in contrast, are clearly lower than at any period in the long records. The analysis method is insensitive to the choice of base period, another choice producing similar trends but centered around a different base.

All the last three sections consider extremes in different ways, but all show similar conclusions. Until the recent 35 years, the warming of the twentieth century is mostly manifest, not by increases in warm extremes, but by reduction in cold extremes. Cold extremes often pass by unnoticed by the majority, except in sectors and seasons where they have important effects.

The Last 150 Years in the Context of the Last 1000 Years

Global average surface temperature has clearly risen over the last 160 years (Figure 1), but what significance does this have when compared to changes over longer periods of time? The last millennium is the period for which most is known about the preinstrumental past, particularly spatially, but it must be remembered that such knowledge is considerably poorer than since 1850. The millennium, particularly the last 500 years, is also the most important when considering attribution of

Figure 6 Numbers of cold days (<10th percentile) and warm days (>90th percentile) for four European locations with long daily records (Stockholm and Central England). The smooth curves highlight variations on decadal timescales (red for warm days and blue for cold days).

recent changes to human influences. Earlier millennia are also important, but they are known to have experienced longer timescale changes in solar irradiance caused by orbital changes (the Milankovitch effect), giving, for example, higher irradiance in summer to northern high latitudes around 9000 years ago. Such differences in insolation mean that comparisons to today are not fair. Summers 9000 years ago in the higher latitudes of the Northern Hemisphere (NH) were warmer, but they experienced an 8% greater amount of solar insolation compared to today.

Information about the past millennium comes from a variety of high-frequency and low-frequency proxy sources. High-frequency sources, giving information on the annual timescale include early instrumental records (back to the late seventeenth century in Europe), written historical documents (mainly Europe and the Far East), tree ring densities and widths (mid-to-high latitudes of both hemispheres), ice cores (both polar ice caps and also high-elevation tropical and smaller polar latitude ice caps), corals (tropical), and some highly

resolved lake and marine sediments. Low-frequency (decadal to century timescale change) evidence comes from boreholes, glacial advances/retreats and peat, lake, and marine cores. Uncertainties in all proxy information are considerable, both because evidence is restricted to where these written and natural archives survive, and more importantly, all proxy records are only imperfect records of past temperature changes.

The last two decades have seen a dramatic improvement in both the availability of past evidence and also in information from diverse regions and sources. Figure 7 compares several different reconstructions of NH temperature change for most of the last millennium. The reconstructions are of different seasons, so based on the instrumental record they would be expected to differ somewhat. None of the series are strictly independent of each other, as they contain some common sources, but each has made different assumptions in their averaging. The most striking feature of the multiproxy averages is the warming over the twentieth century, both for its magnitude and duration. Agreement with the instrumental record

Figure 7 Reconstructions of NH temperatures from several different combinations of proxy data (multiproxy averages). All the series have been smoothed with a 40-year Gaussian filter and all are plotted as departures from the 1961–90 average. The different reconstructions are shown by the colored lines, the black being the instrumental record for April–September for the NH. All the series have been assembled recently and represent cutting edge research in paleoclimatology.

should be assumed, as all the components of the series have, to some extent, been calibrated against instrumental data, either locally or as a whole. The twentieth century was the warmest of the millennium and the warming rate during it has been unprecedented.

The number of series averaged together in each reconstruction depends on the particular study. Some use as many as possible, while others are restricted to specific proxy types (e.g., trees) or limited so that all proxies extend back a thousand years. Even the most spatially extensive studies only incorporate in number less than 5% of the number of instrumental sites. At the temporal scale plotted in Figure 7, however, the number of contributing proxy series is adequate to reconstruct large-scale temperatures, much more so for the NH compared to the Southern Hemisphere (SH), so Figure 7 only considers the NH. If standard errors are assigned to these series, as was the case for the instrumental period, errors would be considerably larger even for the 50-year timescale plotted.

Earlier studies, using considerably fewer proxy datasets, have considered the past millennium and two periods, the Little Ice Age (variously defined as AD 1450–1850) and the Medieval Warm Epoch (less well-defined in the literature, but AD 900–1200 encompasses most earlier works) are often discussed. To some extent, these two periods have become accepted wisdom but the various curves in Figure 7 indicate only partial support. Spatial analysis of the proxy data shows that no century-scale periods in the millennium were universally colder or warmer everywhere, with considerable variability being present. The latter is to be expected even by studying the instrumental period since 1850. Just as the early 1940s were warm in many parts of the world Europe was cold, the early seventeenth century was cool in many regions, but was relatively mild in Iceland. In many respects, therefore, paleoclimatology is in the process of reassessing the evidence for these past periods and further changes are in prospect as more evidence becomes available.

The various series in Figure 7 differ in some respects with regard to the coldest and warmest periods of the millennium, but they have all analyzed orders of magnitude more data than available in the early 1970s. The cooler centuries of the millennium were the sixteenth to the nineteenth, the seventeenth being the coldest in Europe, and the nineteenth coldest in North America. These regions are still the best studied and it will be vital in future to extend the knowledge to other areas, particularly in the SH. At present, for every one long SH proxy reconstruction there are at least 10 in the NH. Just as with the instrumental record it is important to gain as much evidence from as many regions as possible, if how global and hemispheric temperatures have varied over this long time are to be fully understood. Contrasts in the timing of changes between regions and particularly between the hemispheres must be recognized if the causes of the changes are to be fully

understood. A more complete understanding of the causes of the changes will allow to determine how much climate can change naturally, enabling to better distinguish the degree of human influence on surface temperature during the twentieth century.

Sea Level Change

RS Nerem, University of Colorado, Boulder, CO, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

Sea level rise is expected to become a serious problem in the future as the Earth warms. Changes in global average sea level are an excellent indicator of how the Earth is responding to climate change because it responds to the melting of land ice and increases in ocean heat content. Satellite altimeter and gravity measurements have revolutionized how we monitor and understand sea level change. Currently, sea level is rising at a rate of $\sim 3 \text{ mm year}^{-1}$ with roughly equal contributions from thermal expansion, the melting of ice in Greenland and Antarctica, and the melting of mountain glaciers.

Introduction

Sea level rise is likely to be a serious socioeconomic problem in the future as inundation impacts coastal populations and the threat from storms increases. But it is also an excellent indicator of changes in the water reservoirs on the Earth as they respond to climate change. As such, sea level change has emerged as one of a handful of sensitive climate indicators that reveals how the Earth's water reservoirs are changing. Sea level can change due to a variety of factors including the ocean tides, changes in ocean circulation, changes in atmospheric pressure, and a variety of other phenomena, but long-term sea level change is mainly influenced by changes in the heat content of the oceans (thermal expansion) and the exchange of water between the oceans and the continents (Cazenave and Nerem, 2004). Variations in global mean sea level (GMSL) are often used to characterize the climate aspects of sea level change, because much of the natural variability of sea level averages out in the global average. Changes in land water storage, mainly due to changes in precipitation patterns, are the leading cause of interannual GMSL variations, while the melting of land ice (and subsequent run off into the ocean) is the dominant cause of long-term GMSL change, along with thermal expansion. Thus, as the Earth warms, sea level change is a critical climate variable that reflects the amount of heat absorbed by the oceans and land-based ice.

While GMSL may be a critical climate variable, regional sea level change can be quite different from the global mean, and thus is the critical variable for assessing the socioeconomic impacts of the change. In addition, the regional pattern of sea level change may offer clues as to the cause of the changes, which is important for predicting the magnitude and regional variations of future sea level change. For sea level science, accurate global observations of sea level, ocean heat content, and land ice changes are the key for better understanding how the Earth system is responding to climate change and how much sea level might rise in the future. Fortunately, such an observation system has become a reality over the last few decades.

Observations of Sea Level Change

Prior to the satellite era, tide gauge and salt marsh measurements were the primary methods for determining changes in sea level (Woodworth et al., 2011). Tide gauge

measurements have been used to reconstruct GMSL back to 1700 (Figure 1(c)), although only a few gauges extend to the 1700s. Salt marsh measurements have generally corroborated the tide gauge record (Figure 1(b)). While many of our best long-term sea level records come from tide gauge measurements, they are limited by poor spatial distribution and are influenced by vertical land motion at the tide gauge site. Because tide gauges measure sea level change relative to the land, the data are often referred to as 'relative' sea level change measurements. The vertical land motion is important for assessing regional sea level impacts, but it confuses the issue when one is trying to detect true climate signals. Nevertheless, tide gauges provide one of the few direct measurements of sea level change prior to the 1990s, and so attempts are often made to correct the data for the effects of vertical land motion – either through modeling (such as models of glacial isostatic adjustment (GIA)) or through measurements (e.g., using a Global Navigation Satellite System (GNSS) receiver to measure the vertical land motion directly). There have been many different analyses of the tide gauge sea level record (Figure 1(b)). Averaged over the last century, tide gauges generally show that sea level has been rising at an average rate of $\sim 1.8 \text{ mm year}^{-1}$. However, the tide gauge record has provided little insight into the spatial variability of sea level change because of its limited geographic distribution.

The precision satellite altimeter era began in the early 1990s. The launches of TOPEX/Poseidon (1992), Jason-1 (2001), and Jason-2 (2008) into identical orbits with special attention paid to calibration and validation of the measurements have led to a 20-year climate data record of sea level change with a 10-day temporal resolution. The record of GMSL from these missions (Figures 1(d), and 2) has provided a fundamental indicator for how climate change is affecting the Earth system. The average rate of sea level rise over 1993–2013 is $3.2 \pm 0.4 \text{ mm year}^{-1}$. The error is mostly driven by errors in the calibration of the instruments, which is accomplished by locally comparing tide gauge sea level measurements to the altimeter measurements (Mitchum, 2000; Nerem et al., 2010). GMSL also shows significant interannual variability, much of which has been shown to be related to El Niño – Southern Oscillation (ENSO) processes (Boening et al., 2012; Fasullo et al., 2013; Nerem et al., 2010, 1999) through changes in land/ocean precipitation and other factors.

The satellite measurements also allow one to determine the geographic variation of the 20-year sea level rates (Figure 3). This

Figure 1 (a) Paleo sea level data from salt marshes since 1700 from Northern and Southern Hemisphere sites compared to sea level reconstruction from tide gauges (blue time series with uncertainty). The effects of GIA have been removed from these records. Green and light green = North Carolina, orange = Iceland, purple = New Zealand, dark green = Tasmania, brown = Nova Scotia. (b) Yearly average GMSL reconstructed from tide gauges (1900–2010) by three different approaches (orange, blue, and green). (c) Altimetry data sets from five groups with mean of the five shown as bright blue line. (d) Comparison of the paleo data from salt marshes (purple symbols, from panel a), with tide gauge and altimetry data sets (same line colors as in panels b and c). Figure 13.3 from Intergovernmental Panel on Climate Change (IPCC) AR5 WG1.

shows considerable geographic variation ($\pm 10 \text{ mm year}^{-1}$) relative to the global mean rate of 3 mm year^{-1} . Much of this is related to the Pacific decadal oscillation (PDO), and will presumably average out as longer time series become available (Hamlington et al., 2013). The current regional rates of sea level change are dominated by steric sea level changes (Woodworth et al., 2011); however, as the loss of land ice accelerates, it is eventually expected to dominate the patterns of regional sea level change. These patterns will be driven by the magnitude and location of the ice mass loss, creating ‘ice sheet fingerprints’ (Figure 4) in the geographic patterns of regional sea level change (Tamisiea and Mitrovica, 2011). Because loss/gain of land ice can change the Earth’s gravity field and the loading on the solid Earth, regional sea level is changed due to changes in the geoid and vertical land motion.

Satellite altimeter measurements have been invaluable for measuring changes in total sea level, but they offer only limited insight into the causes of that change. Specifically, a better understanding is desired of how much is due to

thermal expansion versus the melting of land ice. The launch of the Gravity Recovery and Climate Experiment (GRACE) in 2002 has revolutionized our understanding of the contribution of land ice and water storage variations to sea level change. GRACE provides monthly maps of the Earth’s time-varying gravity field with a spatial resolution of $\sim 300 \text{ km}$ and an accuracy of 1 cm water equivalent. GRACE has allowed the measurement of ice mass loss since 2002 over Greenland (0.6 mm year^{-1}), Antarctica (0.3 mm year^{-1}) (Velicogna and Wahr, 2013), and from mountain glaciers (0.4 mm year^{-1}) (Jacob et al., 2012). In addition, GRACE has allowed the determination of changes in global mean ocean mass (1.8 mm year^{-1}) (Chambers et al., 2004; Chambers et al., 2010) (Figure 2).

While satellite altimeter and gravity measurements have revolutionized the field of sea level science, improved *in situ* measurements of ocean heat content have also taken a leap forward. Our knowledge of changes in ocean heat content has improved significantly in the last decade with the deployment of the Argo network of profiling floats (Leuliette and Willis,

Figure 2 Global mean sea level variations from TOPEX/Poseidon, Jason-1, and Jason-2 altimeter measurements. Seasonal variations have been removed, an inverted barometer correction has been applied, glacial isostatic adjustment is removed, and 2-month smoothing is applied. Reproduced with permission from <http://sealevel.colorado.edu>. Global mean ocean mass variations computed from the GRACE satellite gravity mission (<http://xena.marine.usf.edu/~chambers/SatLab/Home.html>). Seasonal variations and glacial isostatic adjustment have been removed, and 2-month smoothing has been applied.

2011). Prior to Argo, shipboard hydrographic measurements (XBTs, etc.) are used. These measurements suggest that the contribution of thermal expansion in the upper ocean to GMSL over the last two decades is $\sim 1 \text{ mm year}^{-1}$. Much less is known about the heat absorbed by the deep ocean, and a major goal of future research is to better determine that contribution to sea level change.

Causes of the Observed Sea Level Change

Changes in GMSL are primarily driven by changes in ocean heat content (thermal expansion), land water storage, and the

Figure 3 Regional variations in the rate of sea level change over 1993–2013. Reproduced with permission from <http://sealevel.colorado.edu>.

melting of land-based ice. Interannual changes in GMSL have been shown to be primarily driven by changes in land water storage, which are in turn driven by changes in land/ocean precipitation (Boening et al., 2012; Fasullo et al., 2013; Nerem et al., 2010, 1999). However, there is little evidence for long-term GMSL trends related to land water storage, except for those due to the building of artificial water storage reservoirs on land, which reduces sea level rise (e.g., Chao et al., 2008).

Together, satellite altimetry, GRACE data, and Argo data can be used to ‘close’ the sea level budget over the time period when all three observation systems were active. Roughly, ocean mass (GRACE) plus steric changes (Argo) should equal total sea level change (altimetry). This has in fact been demonstrated within the errors of these systems (Leuliette and Willis, 2011). Over the GRACE time period, Greenland and Antarctica are estimated to have contributed 0.6 and 0.3 mm year^{-1} , respectively, to GMSL change (Shepherd et al., 2012; Velicogna and Wahr, 2013), with the remaining mountain glaciers contributing 0.4 mm year^{-1} (Jacob et al., 2012). Decadal variability related to the PDO could have contributed an additional 0.5 mm year^{-1} over this time period (Hamlington et al., 2013). Global ocean mass (which reflects the total land/ocean mass exchange) is increasing at a rate of 1.8 mm year^{-1} since 2002 (Chambers et al., 2004; Chambers et al., 2010). While the advent of GRACE and Argo measurement systems has been a huge advance for sea level science, their use for improving our understanding of sea level change is limited until longer time series are available from these systems.

Although the contributions vary somewhat depending on the time period considered, during the altimeter era (1992 to

Figure 4 Model output showing relative sea level change due to uniform melting of the Greenland Ice Sheet and the West Antarctic Ice Sheet at rates of 0.5 mm year^{-1} each (giving a global mean value for sea level rise of 1 mm year^{-1}). The modeled sea level changes are less than the global mean value in areas near the melting ice but enhanced further afield. IPCC AR5 FAQ13.1, Figure 2, Adapted from Milne, G.A., Gehrels, W.R., Hughes, C.W., Tamisiea, M.E., 2009. Identifying the causes of sea-level change. *Nature Geoscience* 2, 471–478.

present) the rate of global sea level rise (3.2 mm year^{-1}) can roughly be ascribed to (1) thermal expansion ($\sim 1 \text{ mm year}^{-1}$), (2) Greenland and Antarctica ($\sim 0.9 \text{ mm year}^{-1}$), (3) mountain glaciers (0.8 mm year^{-1}), and (4) decadal variations that appear as trends over the 20-year record ($\sim 0.5 \text{ mm year}^{-1}$) with much smaller contributions from halosteric changes, hydrologic variations in land water storage, and the construction of artificial reservoirs.

Projections of Future Sea Level Change

Assessing the potential socioeconomic impacts of sea level change depends on being able to accurately project future sea level change – both the global average and its regional variation – in addition to many other factors (Tebaldi et al., 2012). This is generally accomplished with either ‘process-based models,’ which use theoretical concepts and computational methods to simulate the behavior of the Earth systems affecting sea level or ‘semiempirical models,’ which use historical observations of sea level and temperature (or radiative forcing) to project sea level change based on projections of future changes in temperature (or radiative forcing) from global climate models. These models have mainly been used to project changes in GMSL, although projections of regional sea level change can also be done.

The IPCC Fifth Assessment Report (AR5) thoroughly evaluated these two techniques for projecting future sea level (Church et al., 2013) based on different scenarios for changing greenhouse gases and radiative forcing called representative concentration pathways (RCPs). For the projected sea level rise from 2000 to 2100, the process-based models project a rise in GMSL of 53–98 cm for RCP8.5 with a rate of change of $8\text{--}16 \text{ mm year}^{-1}$ during 2081–2100 (Figure 5). RCP2.6 ranges from 28 to 61 cm by 2100 and the other RCP scenarios fall in between these to end members. The two projection techniques tend to give somewhat different results, with semiempirical

models generally projecting higher sea levels than process-based models (Figure 6). The IPCC AR5 assessed both techniques, and evaluated the process-based models as ‘medium confidence’ and the semiempirical models as ‘low confidence.’

These techniques for projecting GMSL change can be extended to project regional sea level change as well. Figure 7 shows projections of regional sea level change for different RCP scenarios from the IPCC AR5 (Church et al., 2013). These were computed by combining projections of thermal expansion from climate models and process-based models of ice mass loss, including the effects of ice sheet fingerprints shown in Figure 4 (Church et al., 2011). The projected regional variations from the global mean (Figure 5) can be significant, especially near the ice sheets, where there is very little sea level rise due to the effects of the fingerprints.

While the year 2100 is often a horizon that is used to evaluate future sea level rise, sea level rise will continue well past 2100 even after greenhouse gas emissions have ceased, because of inertia in the global climate system. Levermann et al. (2013) evaluated the potential for sea level rise over the next several millennia and found that thermal expansion and the melting of Antarctica respond roughly linearly with GMSL contributions of 0.4 and $1.2 \text{ m } ^\circ\text{C}^{-1}$ of warming, respectively. Mountain glaciers and Greenland were found to behave non-linearly, but in a compensating way, with Greenland increasing its contribution after the mountain glacier contribution has decreased (because they have effectively melted out). The total sea level commitment over the next 2000 years was found to be $2.3 \text{ m } ^\circ\text{C}^{-1}$ of warming.

Discussion

Global sea level change is a sensitive indicator of changes in the climate system, because on long timescales it responds mainly to heat being absorbed by the oceans and the ice. Observations of sea level change have shown that sea level is rising in response to

Figure 5 Global sea level rise projections from the IPCC AR5 for different RCP scenarios. RCP8.5 ranges from 0.53 to 0.98 m by 2100 with a rate of change of 8–16 mm year⁻¹ during 2081–2100. RCP2.6 ranges from 0.28 to 0.61 m by 2100. Figure 8 of the SPM for IPCC WG1 AR5.

Figure 6 Projections (5–95%) of global mean sea level rise (m) from semiempirical models for 2081–2100 relative to 1986–2005 for (a) RCP2.6, (b) RCP4.5, (c) RCP6.0, and (d) RCP8.5. Blue bars are results from the models using RCP temperature projections; red bars are using RCP radiative forcing. The numbers on the horizontal axis refer to different literature sources. Also shown for comparison is the median (thick black line) and likely range (horizontal gray bar) from the process-based projections. Figure 13.12 from IPCC AR5 WG1.

Figure 7 Ensemble mean net regional sea level change (m) evaluated from 21 CMIP5 models for the RCP scenarios (a) 2.6, (b) 4.5, (c) 6.0, and (d) 8.5 between 1986–2005 and 2081–2100. Each map includes effects of atmospheric loading, plus land ice, GIA, and terrestrial water sources. Figure 13.20 from IPCC WG1 AR5.

Figure 8 Compilation of paleo sea level data, tide gauge data, altimeter data, and central estimates and likely ranges for projections of global mean sea level rise for RCP2.6 (blue) and RCP8.5 (red) scenarios, all relative to preindustrial values. Figures 13.27 and 13.3 from IPCC AR5 WG1.

the warming of the planet (Figure 8) and that rate is increasing in time. Currently, the rate of GMSL rise is 3.2 mm year^{-1} with the main contributions coming from thermal expansion, the melting of Greenland and Antarctica, and mountain glaciers. However, this rate is expected to accelerate in the coming decades. The IPCC estimates GMSL could rise between 28 and 98 cm this century (Figure 8) depending on how greenhouse gases change in the future. The uncertainties in these projections

are more about how long it will take sea level to rise – the magnitude of the rise is much better understood.

Introduction

The composition of the Earth's atmosphere has changed considerably over geological time but very little is known about how the upper atmosphere and solar–terrestrial interactions responded to these changes. Indeed, it is only since the dawn of the space age that information on the structure of the upper atmosphere and its response to solar–terrestrial influences have been measured. Since the space age began in the 1950s, this does not leave a long record for determining the sensitivity of the upper atmosphere to changes driven by recently observed variations in composition. However, certain measurements and model calculations have made it increasingly clear that releases of trace gases from human activity have a potential for causing a change in the present-day climate of the Earth. Most discussions of the projected change during the past decade have dealt with changes in the Earth's troposphere and stratosphere. There have been many papers written on the subject and several assessment panels have issued reports which indicate that the troposphere will warm and the stratosphere will cool in response to a doubling of the present-day composition of several trace gases, such as carbon dioxide and methane, toward the end of the twenty-first century. Yet not much is known about how the upper atmosphere will respond to these influences. Therefore, the following is based primarily on theoretical considerations and model simulations that await verification by adequate trend measurements of the upper atmosphere properties. The few available observations, however, have suggested that the mesosphere and thermosphere/ionosphere are experiencing a cooling trend over the past few decades.

Trace Gas Influences on the Troposphere and Stratosphere

The amounts of certain trace gases in the atmosphere, such as carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), chlorofluorocarbons (CFCs), and tropospheric ozone (O_3), have been increasing during the past few decades. These gases are mainly transparent to incoming short-wave solar radiation but they absorb and emit long-wave IR radiation and thus are able to influence the Earth's climate. These gases are generally referred to as 'greenhouse gases.' Various projections, based on past and current trends of the rate of emission of these gases, suggest that the present-day concentration of several of these species will double by the end of the twenty-first century.

Most studies dealing with the consequences of the increasing greenhouse gases have been concerned with the troposphere and the stratosphere. These studies suggest that the global mean temperature of the troposphere will increase by 1–5 K and the stratosphere will cool by about 10–20 K in response to a doubling of present day CO_2 concentrations and various increases in other greenhouse gases. The predictions are

based primarily on radiative considerations and there is still considerable uncertainty as to the magnitude of the global response because of uncertainties in cloud feedback, aerosols, and dynamics.

Numerical model studies of the stratospheric response have shown that the combined effects of projected trace gas increases to the end of the twenty-first century will result in major changes to both the ozone and temperature distributions. **Figure 1** shows the results of one such model calculation. For a doubling of the CO_2 concentration alone, the calculated stratopause temperature decreases by 10–15 K. But when chemical feedback is included, the concentration of ozone will increase because certain temperature-dependent chemical rate coefficients are slower at lower temperature. This results in less ozone destruction. Higher ozone concentrations will absorb more solar radiation and thus partially offset the cold temperatures calculated by CO_2 cooling alone thus producing a temperature healing. When the chlorofluorocarbon concentration increases, say from 2.0 to 6.6 ppbv, the ozone in the upper stratosphere decreases about 30–50% and the temperature decreases by 10–15 K. The combined effect of both the CO_2 doubling and the CFC increases is shown in **Figure 1** where the stratopause temperature is seen to decrease by 15–25 K and ozone in the lower mesosphere to increase by 10% due to the healing effect but to decrease by 10–30% in the upper stratosphere because of

Figure 1 Predicted response of the middle atmosphere in June to a doubling of CO_2 and an increase of chlorofluorocarbons from 2.0 to 6.6 ppbv. The contours are temperature difference in degrees K in (a) and percent change in ozone in (b), both from present-day conditions. Reproduced from Brasseur and Hitchman (1998). Stratospheric response to trace gas perturbations: changes in ozone and temperature distribution. *Science* 240: 634–637.

catalytic destruction of ozone caused by CFCs. These results suggest that significant stratospheric change should occur as a result of increased trace gases from present-day levels. CO₂ increases lead to lower temperatures in the middle and upper stratosphere because of increased emission in the infrared radiation to space. In addition, ozone depletions in the middle and upper stratosphere above about 30 km lead to less absorption of ultraviolet radiation, and thereby to less solar heating and enhanced cooling. As a result of the combined effect, the stratosphere is projected to cool significantly.

Trace Gas Influences on the Mesosphere and Thermosphere

There have been a few studies to investigate how the atmosphere above the stratopause might respond to the global change expected to occur in the troposphere and stratosphere. These studies suggest that global change effects are not confined entirely to the lower atmosphere but that significant changes can extend further into the upper atmosphere, affecting the mesosphere, thermosphere, and ionosphere. For a doubling of present-day concentrations of CO₂ and CH₄ mixing ratios, which is expected to occur by the end of the twenty-first century, the global mean temperature of the mesosphere is projected to cool by 10 K and that of the thermosphere to cool by 50–100 K from present-day conditions. The predicted sensitivity of the mesosphere and thermosphere to variations of CO₂ and CH₄ is shown in Figure 2, where temperature departures from the present-day globally averaged temperature structure are shown for a doubling of present-day CO₂ concentrations, which should occur by the end of the twenty-first century, and the halving of present-day CO₂ concentrations that occurred at the end of the last ice age about 18 000 years ago. These predictions indicate a slow response to trace gas increases, yet the few available observation during the past decade indicate that the mesosphere and thermosphere are cooling much more rapidly than suggested by the trace gas predictions, indicating that other factors are involved in the upper atmosphere that are not accounted for in present-day model simulations.

The atmosphere expands as it is heated and contracts as it cools. Therefore, the troposphere should expand slightly as it is warmed by a few degrees, but the upper atmosphere should contract much more because of the greater cooling. As a result, the density at a given height in the upper atmosphere should decrease. The sensitivity of the upper atmosphere density to a halving and doubling of the CO₂ concentrations from present-day concentrations is also shown in Figure 2. The calculations suggest that at a given height in the upper thermosphere, densities were 40–50% larger at the end of the last ice age and should be 40–50% smaller by the end of the twenty-first century for similar solar and auroral forcings. The decrease shown could occur at the end of the twenty-first century and so the density variations could be occurring slowly at the present time. However, recent observations of the decay in the orbits of satellites indicate that the decadal trends in atmospheric drag are occurring faster than model predictions that include only CO₂ doublings. There appears to be missing physics or chemistry in current models if the

Figure 2 (a) Calculated neutral gas temperature (T_n) difference profiles for doubling of CO₂ and CH₄ concentrations (solid line) and a halving of the CO₂ and CH₄ concentrations (dashed line) from present-day concentrations. (b) The compositional response of the major neutral gas constituents of the upper atmosphere. Solid lines are from the doubling of the trace gas concentrations and dashed lines are for halving the concentrations from present-day values. O₂, N₂, and O are molecular oxygen, molecular nitrogen, and atomic oxygen respectively. Reproduced from Roble and Dickinson (1989). How will changes in carbon dioxide and methane modify the mean structure of the mesosphere and thermosphere. *Geophysical Research Letters* 16: 1441–1444.

observations that suggest the current observed rate of atmospheric cooling are correct.

In addition to the changes in the major constituents of the mesosphere and thermosphere, there are significant variations that occur in the concentrations of minor neutral gas constituents such as O₃, H₂O, OH, HO₂, CO, NO, NO₂, N(⁴S), and others. The minor species change because many of the chemical rate constants for these species are highly temperature-sensitive and turbulent diffusion and advective transport, which determine their vertical distributions, depend on the vertical temperature structure. The results show that for a doubling of

CO₂ and CH₄, NO, and O₃ could decrease in the thermosphere and H₂O, N(⁴S), CO, and H could increase. A doubling of the present-day methane concentration could also increase the H₂O and with colder mesopause temperatures could result in an increase in noctilucent clouds. An increase in tropospheric methane of about 1 ppmv could cause an increase in exospheric hydrogen by about 30% with a corresponding increase in the total density in the hydrogen-dominated part of the exosphere.

A change in these species and temperature structure could also have an effect on the ion composition of the D-, E-, and F-ionospheric regions. Even though the atmospheric models that predict these global mean changes are quite sophisticated, there are still many uncertainties concerning the chemistry, reaction rates, and various atmospheric processes, such as turbulence and atmospheric transport by gravity and planetary waves, that suggest caution in evaluating the magnitude of the predicted changes in chemical structure that respond to atmospheric cooling.

In addition to the changes in thermal and compositional structure on a global mean basis, there are also variations in the latitudinal distribution of heat and momentum sources that alter the mean meridional and global circulation patterns from present-day conditions.

Predicted Changes in Ionospheric Structure

The predictions of change in the neutral upper atmosphere could also cause changes in the ionosphere. The thermospheric cooling and associated composition changes could lower the E-layer and F2-layer peaks in the ionosphere by about 2 km and 20 km, respectively. However, the predicted changes in the E-layer and F2-layer electron densities should be small. Changes in the 'maximum usable frequency' for radio propagation should also be small for the trace gas doubling scenario. These changes are consistent with a lowering of the ionosphere as the neutral atmosphere contracts from 'greenhouse cooling.'

There is an important need to continue model development using coupled models of the Earth's atmosphere, ionosphere, and magnetosphere to evaluate the entire atmospheric readjustment to global change induced by human activity.

Do Observations Support the Predictions of Global Change?

In addition to the modeling studies mentioned above, there have been various investigations that suggest that a change in the composition and temperature structure of the upper atmosphere has been taking place in the past few decades. The overall trend in upper atmosphere response is not clear at the present time but a brief summary of some of the observational studies is given below:

- Radiosonde and satellite observations indicate a decadal cooling trend of the global, annual-mean lower stratosphere since about 1980. Over the period 1979 to 1994, its amplitude is approximately 0.6 K/decade in the 15–20 km altitude range.
- The vertical profile of the annual-mean stratospheric temperature change observed in the Northern Hemisphere for the 1979–94 period consists of an approximately 0.75 K/decade cooling of the 15–35 km region, a slight reduction in the cooling at about 35 km, and increased cooling with height above 35 km (approximately 2 K/decade at 50 km).
- In the upper stratosphere and mesosphere, rocket observations made at various Russian and other stations indicate a few degrees of cooling in the 30–40 km region, increasing to 20 K cooling in the mesosphere near 60–70 km. These changes are not only occurring at high latitudes but penetrate to low and equatorial latitudes.
- In the middle and upper atmosphere, both the greenhouse gas increases and observed ozone changes contribute to the cooling. Atmospheric models are currently being used to investigate the observed decadal trends.
- Lidar observations of the height of the atmospheric sodium layer near 90 km suggest that the height of the sodium layer has decreased during the past decade, indicating that the mesosphere temperature has cooled over the same period.
- Observations have suggested that the trend in increasing atmospheric methane has the potential for increasing the water vapor concentration in the middle atmosphere and contributes to an increase in noctilucent cloud formation in the high-latitude summer mesopause region near 82 km. It is well known that water vapor is an important product of methane oxidation in the stratosphere and thus the increasing methane concentration may be responsible for an increase in the number of sightings of noctilucent clouds in recent years. An observed secular increase over the last few decades may, in part, be caused by increasing concentrations of water vapor and colder temperatures in the mesopause region.
- Lidar measurements over the south of France have indicated a secular change in temperature over the 33–87 km altitude range. A –4 K/decade temperature trend in the 60–70 km altitude region between the years 1978 and 1989 has been observed. Ground-based lidar data and satellite temperature data have found a change in mesospheric temperatures with a trend of –0.10 to –0.14 K per year during the 1980–90 period. These measurements also indicated a solar cycle variability that must be considered when evaluating secular trends.
- Observations have shown that the solar cycle variation of stratospheric ozone over the 1979–99 period is about 5% near 40 km altitude. The observed trend in ozone over this period is monotonically decreasing with a 6–8% per decade change.
- Predicted changes in the atmospheric vertical structure that should occur as a result of a doubling of trace gas concentrations could have a significant effect on the gravitational and thermal tides that are excited in the atmosphere. In particular, the effects in the middle atmosphere may be significant.
- An increase in tropospheric methane of 1 ppmv could cause an increase in exospheric hydrogen number density of 30%. Since atomic hydrogen is the dominant species in the exosphere, this suggests that the total exospheric density is sensitive to global change. The increase in exospheric

hydrogen could have important consequences on the plasma density of the magnetosphere, plasma exchange between the magnetosphere and ionosphere, and perhaps solar–terrestrial plasma coupling processes.

- Perhaps the largest uncertainty in the energetics of the upper mesosphere and lower thermosphere is the magnitude of the rate coefficient for deactivation of the bending mode of carbon dioxide by atomic oxygen. There has been considerable uncertainty in the rate of this coefficient, ranging from 2×10^{-13} in early investigations to a value of $6 \times 10^{-12} \text{ cm}^3 \text{ s}^{-1}$ in more recent analyses of satellite data. This coefficient influences the predictions of upper atmospheric response to global change.
- Recent laboratory and satellite data have indicated that certain crucial rate coefficients important for the energy balance of the upper atmosphere have changed considerably, suggesting that the overall aeronomy of the upper atmosphere is still not sufficiently known. The photodissociation coefficient for nitric oxide and the O–NO vibration deactivation rate coefficient have changed recently, which, along with the uncertainty of the CO_2 –O rate coefficient, makes accurate predictions of upper atmosphere global change difficult at least until these aeronautical issues are resolved.

- Will present-day solar–terrestrial couplings be altered by changed upper atmosphere and ionosphere structures?
- Will new upper atmosphere chemical and physical processes become important as a result of an altered atmospheric structure (e.g., heterogeneous chemistry was found to be important for understanding changes in the Antarctic ozone hole)?
- Will an altered upper atmosphere structure have important feedback on the troposphere and weather systems?
- Will present-day technological systems have to be redesigned to adapt to a changed upper atmosphere environment?

These are only a few of the many questions that emerge from the realization that the present-day upper atmospheric structure may be changing.

Future Studies

The studies described have been motivated by the realization that global change is not confined only to the lower atmosphere but that the consequences of man's activities may be more global and extend into the upper atmosphere and even affect plasma processes that couple the solar wind into the Earth's upper atmosphere. Indeed, the application of current, well-tested models of the upper atmosphere suggests that significant changes to the present-day structure of the atmosphere above about 50 km will occur by the middle of the twenty-first century. The studies conducted thus far are only suggestive of possible changes and there is an important need for further investigations and long-term measurements to detect natural and anthropogenic trends into the twenty-first century.

Studies of the possible effect of global change on the upper atmosphere are in their infancy and a number of important questions emerge:

- Will gravity wave, tidal, and planetary wave propagation characteristics change in response to an altered atmospheric structure?
- How will energy, mass and momentum exchange rates between atmospheric regions change in response to increased CO_2 cooling and a contracted upper atmosphere?

Synopsis

The terrestrial biosphere interacts with the atmosphere through exchanges of trace gases and of energy. These interactions are bidirectional, with atmospheric conditions modifying ecological controls of trace gas and energy exchange, and the very exchanges feeding back to affect atmospheric chemistry and climate. This article addresses the role of biosphere–atmosphere material and energy exchange in atmospheric processes, the biological processes involved, and how biotic responses to ongoing and future global changes could influence the future chemical and radiative balance of the atmosphere.

Introduction

The terrestrial biosphere interacts with the atmosphere through exchanges of trace gases and of energy. These interactions are

bidirectional, with atmospheric conditions modifying ecological controls of trace gas and energy exchange, and the very exchanges feeding back to affect atmospheric chemistry and climate (Figure 1). Here, we review the role of

Figure 1 Interactions between the terrestrial biosphere and the atmospheric composition and climate (plain type, thin arrows), and impacts of global environmental change on the coupled biosphere–atmosphere system (bold italics, thick arrows). Climate influences biophysical and biogeochemical processes, creating feedback effects to both atmospheric composition and climate through fluxes of heat, water, and trace gases. Global changes such as N deposition, acid rain, enhanced UV-B radiation, and rising CO₂ directly affect ecosystem biogeochemistry, feeding back to the atmosphere through altered trace gas fluxes, altering ecosystem structure by favoring some species over others, and affecting biophysically mediated exchanges of energy by altering physiological processes (e.g., stomatal conductance). Other global changes affect ecosystem structure directly, with, for example, invading species introducing new biological entities with unique contributions to biogeochemical and biophysical properties. Modified from Sellers, P.J., et al., 1991. Charting the boreal forest's role in global change. EOS Transactions American Geophysical Union 72 (4), 33–40.

biosphere–atmosphere material and energy exchange in atmospheric processes, the biological processes involved, and how biotic responses to ongoing and future global changes could influence the future chemical and radiative balance of the atmosphere. Global environmental change is already altering biological production and consumption of trace gases and energy partitioning between the biosphere and the atmosphere. However, the magnitude and direction of these effects are not well constrained, and this uncertainty contributes to the difficulty in predicting future global climate. Global changes likely to substantially alter biosphere–atmosphere trace gas and energy exchange include climate change, rising atmospheric CO₂, acid rain and associated nitrogen deposition, species invasions, losses of biodiversity, and land use and land cover change (Figure 1).

Trace gases in the atmosphere are arbitrarily defined as gas species with concentrations equal to or less than that of carbon dioxide (388.5 ppmV, average concentration for 2010). Through biogeochemical transformations in terrestrial ecosystems, plants and soil microorganisms produce and consume many trace gases, often at rates high enough to affect atmospheric concentrations. Climate is a key determinant of biogeochemical transformations, and thereby directly affects rates of trace gas exchange. Because species differ in their physiological capacities to produce and consume trace gases, the suite of organisms comprising a biological community and the number of organisms present in an ecosystem both strongly influence biogeochemical cycling and associated trace gas fluxes. In turn, biogeochemical transformations include processes that regulate nutrient availability to plants, thereby influencing species composition and ecosystem structure and productivity. Energy exchanges between ecosystems and the atmosphere include fluxes of sensible heat and latent heat (i.e., evaporation of water), exchanges that are directly mediated by the biophysical properties of ecosystems. Like biogeochemical transformations, biophysically mediated energy exchange is sensitive to climate and to the physiological properties of organisms, mostly plants. Thus, changes in climate and in the structure of terrestrial ecosystems alter patterns of biosphere–atmosphere energy exchange.

Trace Gases

Carbon Dioxide

The concentration of carbon dioxide (CO₂) in the atmosphere is increasing by 0.5% per year (1980–2008), a rate unprecedented for the last 400 000 years. A heat-trapping or greenhouse gas, CO₂, is estimated to be responsible for 60% of current global warming and that which is predicted to occur over the next several hundred years. While the current increase in CO₂ concentrations is clearly driven by human activities (fossil fuel burning, deforestation, and cement manufacture), two biological processes strongly influence the concentration of CO₂ in the atmosphere. Photosynthesis by plants (including algae) converts atmospheric CO₂ to organic carbon, and this process is the primary entry point of carbon into the biosphere. Respiration by plants, animals, and microorganisms oxidizes organic carbon, returning it to the atmosphere as CO₂. Photosynthetic and respiratory rates

of CO₂ exchange between the terrestrial biosphere and the atmosphere amount to roughly 120 Gt C year⁻¹, compared to about 9.5 Gt C year⁻¹ added through the combined anthropogenic effects of fossil fuel burning, land use change, and cement manufacture. Thus, predicting the future trajectory of atmospheric CO₂ concentrations requires understanding how global changes might alter the balance between CO₂ release to the atmosphere versus CO₂ uptake and storage in ecosystems.

Spatial and seasonal changes in atmospheric CO₂ concentration reflect the balance of photosynthesis and respiration in the terrestrial biosphere. For example, photosynthesis is a larger flux than respiration during the growing season, and this imbalance is reflected in lower atmospheric concentrations of CO₂ during the spring and summer. This pattern is most pronounced above the temperate zone in the northern hemisphere (Figure 2); less so in the southern hemisphere, where landmasses are smaller; and essentially absent in tropical regions, where the activities of photosynthesis and respiration tend to be synchronous throughout the year. Oceanic exchanges of CO₂, while large, do not show strong seasonality. These seasonal oscillations in atmospheric CO₂ concentration reflect the metabolism of the terrestrial biosphere and underscore the importance of biological control over atmospheric CO₂ concentrations.

Global change can alter these biological controls, affecting fluxes of photosynthesis and respiration and thus the net exchange of carbon between the biosphere and atmosphere. Several lines of evidence suggest that such changes are already underway. The amplitude of the seasonal oscillations in atmospheric CO₂ has increased over the past 40 years, particularly above the northern hemisphere, indicating greater interannual variation in activity of the terrestrial biosphere in this region. Inverse modeling of atmospheric CO₂ concentration, stable carbon isotope composition (¹³C/¹²C), and a number of land-based measurements of biosphere–atmosphere CO₂ exchange indicate a net sink for atmospheric CO₂ in the northern hemisphere. While land use change in the tropics currently amounts to a substantial source of CO₂ to the atmosphere, on the order of 1.1 Gt C year⁻¹, this is partly offset by afforestation of abandoned agricultural lands in the northern hemisphere and net uptake of CO₂ by forests. Experimental additions of either CO₂ or N often stimulate ecosystem carbon uptake, at least in the short term, suggesting that globally pervasive N deposition and increasing atmospheric CO₂ may already be contributing to the terrestrial CO₂ sink. For 2009, this terrestrial carbon sink is estimated to have been 2.4 Gt C year⁻¹. However, it is unclear whether this terrestrial sink will persist. For example, because photosynthesis is less sensitive to temperature than are respiration and microbial decomposition of plant residues, future stores of organic C in soils could decline by up to 11 Gt C globally for every 1 °C of warming. Particularly at high latitudes, the combination of warming and drying could stimulate CO₂ release from tundra and peat bogs, ecosystems that contain most of the world's soil carbon. Furthermore, while experimental CO₂ and N fertilization increases ecosystem CO₂ uptake in the short term, photosynthesis shows a saturating response to rising CO₂, and excessive N deposition often decreases soil fertility and plant production. Because of the

Figure 2 Three-dimensional representation of atmospheric carbon dioxide in the marine boundary layer. The surface represents data that are smoothed in time and latitude. slow turnover time of soil organic carbon, increased carbon uptake observed in experiments tends to overestimate the long-term potential for ecosystem carbon storage.

Methane

Methane (CH_4) is also a heat-trapping gas, contributing roughly 15% to the radiative forcing associated with global warming. As with CO_2 , two biological processes are important in the production and consumption of atmospheric CH_4 : methanogenesis and methanotrophy. Methanogenesis is the largest source of CH_4 to the atmosphere and is conducted by strictly anaerobic microorganisms of the domain Archaea. Methanogens thrive in many habitats where oxygen concentrations are low, including wetlands, sediments in aquatic ecosystems, and the guts of termites and ruminant mammals. Methane produced by soil microorganisms can be released by plant leaves, and a small amount of methane is produced by UV degradation of plant pectins. With intensification and extensification of livestock farming and rice cultivation, humans have increased methanogenic activity and associated CH_4 emissions to the atmosphere. Fossil fuel mining and biomass burning are additional important anthropogenic sources of CH_4 to the atmosphere. While natural sources add around $160 \text{ Tg CH}_4 \text{ year}^{-1}$ to the atmosphere, anthropogenic sources are larger, totaling nearly $375 \text{ Tg CH}_4 \text{ year}^{-1}$. Most CH_4 is destroyed in the atmosphere through interactions with OH radicals or is lost to outer space. However, methanotrophs – literally ‘methane eaters’ – are an additional important global CH_4 sink, consuming as much CH_4 as accumulates in the atmosphere each year (40 Tg) and constituting approximately 10% of the global CH_4 sink. Methanotrophs are bacteria that oxidize CH_4 to generate energy and fix CO_2 into organic compounds. Methanotrophs are widespread in nature, and are quantitatively important in the global CH_4 cycle in well-aerated surface soils of terrestrial ecosystems. Many temperate forests,

for example, are net CH_4 sinks, consuming CH_4 from the atmosphere.

Global change has the potential to increase or reduce CH_4 production in soils. For example, global changes that increase plant production, such as elevated CO_2 , often stimulate CH_4 efflux from wetlands, because increased plant production in wetlands enhances substrate availability for anaerobic decomposition, stimulating CH_4 production. In experiments, elevated CO_2 often reduces transpiration (water loss) from wetland plants, raising the water table in wetlands and enhancing anaerobic conditions, again potentially stimulating CH_4 efflux. In the arctic, thawing of permafrost may already be stimulating CH_4 emissions by increasing methanogenic activity in previously frozen soils. By contrast, if warming causes widespread drying of wetlands and tundra, anaerobic activity could decline and rates of methane oxidation increase.

Globally, methane oxidation in soils is a smaller flux than methane production, and changes in methane oxidation are likely to have less influence on atmospheric concentrations than are changes in methane production. Some evidence points to a diminished capacity of terrestrial ecosystems to consume atmospheric CH_4 with increasing atmospheric CO_2 concentrations, but the magnitude of this effect appears to be negligible at the global scale. By increasing soil water content (through reduced transpiration) and thereby reducing CH_4 diffusion into soil, elevated CO_2 has been shown to reduce rates of CH_4 oxidation by forest soil. In another case, CH_4 consumption rates declined in CO_2 -treated forest plots even without a change in soil water content or any other obvious mechanism, raising the possibility of reduced efficiency in CH_4 oxidation due to changes in the methanotrophic bacteria community. Reduced CH_4 oxidation has also been observed in grasslands exposed to elevated CO_2 . Thus, reduced CH_4 uptake may be a general consequence of rising atmospheric CO_2 .

Land use change is likely to reduce the terrestrial CH_4 sink: converting forests, woodlands, and savannahs to cultivated or

grazed lands reduces CH_4 uptake, sometimes even causing a shift from net methanotrophy to net methanogenesis. Continued expansion of agriculture and livestock husbandry is likely to further reduce the soil CH_4 sink. Acid deposition also decreases CH_4 oxidation, due to physiological responses of methanotrophs to low soil pH, and also, in the case of nitrogen deposition, to inhibitory effects caused by increased NH_4^+ availability in soil. Ammonium-oxidizing bacteria (nitrifiers; see the “Oxides of Nitrogen” section) have the capacity to oxidize methane, because of structural similarities in the ammonia- and methane-binding enzymes. For this reason, it is not always apparent which groups of organisms are responsible for methane oxidation in soils. Compared to methanotrophs, however, nitrifiers have a lower affinity for CH_4 and therefore oxidize CH_4 more slowly, so displacement of methanotrophs by nitrifiers in response to N deposition may exacerbate inhibition of CH_4 oxidation by ammonium. The inhibitory effects of NH_4^+ on methane oxidation may also explain the reduced capacity for CH_4 oxidation following land use change, as NH_4^+ availability often increases after land clearing or because of direct application of nitrogenous fertilizers.

Oxides of Nitrogen

Nitrous oxide (N_2O) is a potent greenhouse gas, with 300 times the warming potential of CO_2 on a molar basis. N_2O concentration in the atmosphere is increasing at a rate of 0.3% per year, and it is responsible for around 5% of the radiative forcing associated with global warming. N_2O also plays a critical role in stratospheric ozone depletion. Nitric oxide (NO) and nitrogen dioxide (NO_2), together referred to as ‘ NO_x ’ are important reactive gases, influencing tropospheric concentrations of O_3 , OH, HNO_3 , and CH_4 . While their effects on atmospheric processes fundamentally differ, N_2O and NO_x are produced and consumed by the same groups of organisms, and so these gases are treated together here.

Nitrification and denitrification are the two major biological sources of N_2O and NO_x . Nitrifying bacteria use ammonia (NH_3) as an energy source, oxidizing it to nitrate (NO_3^-). Like methanotrophs, which oxidize CH_4 , nitrifiers use their substrate (NH_3) to fix carbon in a manner analogous to a plant’s use of light in photosynthesis. Incomplete oxidation of NH_3 results in gaseous losses of nitrogen dioxide (NO_2), nitric oxide (NO), and N_2O ; emissions of these oxides of nitrogen to the atmosphere can account for as much as 5% of the total nitrification flux. Denitrifying bacteria respire NO_3^- , using it as a terminal electron acceptor just like animals (and other aerobic organisms) use O_2 . In the process, denitrifiers reduce NO_3^- to N_2 gas, with several intermediates, including NO_2 , NO, and N_2O . The final step in the denitrification chain is reduction of N_2O to N_2 , a step that is often incomplete, such that gaseous N_2O escapes from the reaction site. NO_x , too, can be emitted during the earlier steps. Complete denitrification can also consume both N_2O and NO_x and other reports suggest that NO_x consumption by other (nondenitrifying) soil microorganisms may serve a detoxifying function, or may have no clear physiological role (co-metabolism). However, it is not clear that net N_2O or NO_x consumption by soils has any major influence on the global budget of these trace gases. Plants also

play a role in atmospheric NO_x : both uptake and emission of NO_2 by plant leaves are known to occur.

Gaseous losses of NO_x and N_2O during nitrification and denitrification represent small proportions of the total flux of N through these pathways. Nevertheless, the quantities produced are appreciable for the global fluxes of these important trace gases. Globally, soils amount to 65% of total atmospheric sources of N_2O and 40% of NO_x . Tropical (N_2O), wetland (N_2O), arid (NO_x), and cultivated (both) systems are the major soil contributors of these important trace gases. Rates of N_2O production by soils are likely to increase with climate warming, because, like most biological reactions, N_2O production is temperature sensitive and has been found to increase in response to experimental warming in a number of cases. A lowering of the water table in tundra and peatlands associated with warming increases N_2O emissions, likely because the slightly more oxidizing conditions favor incomplete reduction of NO_3^- during denitrification, increasing the amount of N_2O lost in the reaction chain. Conversion of tropical forests to pasture, one of the more prevalent land use changes in the tropics, usually decreases N_2O losses from soils. However, pasture reclamation, which often involves fertilizer application, can cause N_2O fluxes to return to or even exceed levels typical of native forests. Additionally, conversion of native ecosystems to agriculture often dramatically increases N_2O losses from soils. Thus, ongoing global changes are likely to increase rates of N_2O accumulation in the atmosphere.

Emissions of NO_x to the atmosphere are also increasing, particularly from cultivated (and fertilized) soils. As with N_2O , land clearing, cultivation, and fertilization in agriculture increase soil emissions of NO_x , and global increases in these land use changes are increasing the soil source of these reactive gases. Rising atmospheric CO_2 has been shown to reduce NO_x fluxes associated with nitrification by increasing the demand for NH_3 by nonnitrifying microorganisms, reducing substrate availability for nitrifiers. By contrast, warming and N deposition are both likely to increase NO_x fluxes from terrestrial ecosystems.

Other Trace Gases

Carbon monoxide (CO) affects atmospheric chemistry by contributing to tropospheric ozone formation and interfering with methane destruction in the stratosphere. Up to 3% of net primary productivity can be lost as direct CO emission by plants or as losses of volatile organic hydrocarbons (VOCs) subsequently oxidized to CO. Soils are both an important source and sink of CO to the atmosphere. A number of bacteria are capable of oxidizing CO to CO_2 , including some methanotrophs (also important in CH_4 uptake) and nitrifiers (important in N_2O production). Based on selective inhibitor experiments, even eukaryotes may contribute to CO consumption in some forest soils. CO oxidation is sensitive to the water and organic matter content of soils, but is less sensitive to temperature compared to many other ecological processes. While most soils are net CO sinks, some, particularly in arid regions, are net CO producers. The mechanism for CO production is unknown, but it is apparently abiotic, as sterilization often converts a soil from a net CO sink to a source.

Compared to other trace gases, the biology of CO consumption is not very well understood.

Plants emit a number of VOCs to the atmosphere, including isoprenoids (isoprene), terpenes, and oxygenated compounds. These compounds influence carbon monoxide, ozone, and aerosol formation in the troposphere. About half of plant VOC emissions to the atmosphere occur as isoprene. Effects of global change on VOC emissions have not been characterized as well as for other trace gases; nevertheless, changes in VOC emissions are likely to occur. Because plant species naturally differ in rates of VOC production, land use and other global changes that result in shifts in species composition are likely to profoundly alter VOC emissions to the atmosphere. For example, in general, native tropical forest trees produce more isoprene than either crops or pasture grasses, such that land clearing for agriculture or grazing likely reduces VOC emissions. Secondary forests, however, contain many species with high rates of VOC emissions, and net emissions from secondary forests may exceed those from primary forests in some cases. For this reason, land use change could cause VOC emissions to the atmosphere to increase or decline. Isoprene and terpene emissions increase exponentially with temperature, and are thus likely to increase in response to global warming. Global changes that increase plant production (CO_2 and N deposition) are also likely to increase VOC production. In concert with emissions of NO_x from combustion and fertilizer application, increased VOC emissions could increase concentrations of tropospheric ozone and carbon monoxide.

Carbonyl sulfide (COS) is the most abundant sulfur species in the atmosphere. COS is primarily produced abiotically in the oceans; anaerobic production by soil microorganisms occurs, particularly in salt marshes, but is a small source globally. In the stratosphere, COS is oxidized by photolysis to sulfate aerosols, forming an aerosol layer important in cooling the planet, and also in enhancing depletion of stratospheric ozone through chemical interactions with nitrogen and chlorine species. Biological uptake of COS by soils has been

documented, but its significance on a global scale is not well constrained. Lichens are also capable of COS uptake, likely representing a small but nontrivial sink. Uptake by terrestrial vegetation is the major global sink for COS (Table 1). Based on enzyme inhibition studies, COS uptake is likely mediated by carbonic anhydrase, an enzyme that occurs in plants, lichens, and bacteria. COS enters higher plants through stomata, and there is some evidence that reduced stomatal aperture impedes COS uptake by vegetation. Thus, global changes that reduce stomatal conductance (e.g., increasing atmospheric CO_2) may reduce the terrestrial COS sink, possibly constituting a negative feedback to global warming. By contrast, COS uptake in lichens apparently increases with temperature, a possible positive feedback to global warming.

Water and Energy Exchange

Terrestrial ecosystems interact with the atmosphere through exchanges of energy, moisture, and momentum at all temporal and spatial scales. These interactions are functions of key land surface parameters, which derive from the structure and physiology of terrestrial ecosystems. The bidirectional nature of ecosystem–atmosphere interactions is clearly evident. For example, the gas exchange of leaves responds to variation in light, temperature, vapor pressure, and CO_2 partial pressure, and, in turn, affects the water, energy, and trace gas exchange with the atmosphere. Over long periods and broad spatial scales, ecosystem–atmosphere interactions are yet more evident. Water availability and temperature range are the major determinants of the structure and function of terrestrial ecosystems over decades to centuries, and the paleoecological and paleoclimatological records indicate that glacial–interglacial cycles involve coupled changes in the distribution of terrestrial ecosystems, surface albedo, biogeochemistry, and climate. It is understood that the Earth’s climate and ecological systems have interacted over geologic time. Current changes in

Table 1 Trace gases influencing atmospheric chemistry and climate that are produced and consumed by the terrestrial biosphere

<i>Gas</i>	<i>Producing organisms</i>	<i>Terrestrial production</i>	<i>Consuming organisms</i>	<i>Terrestrial consumption</i>	<i>Atmospheric consequences</i>
CO_2	All organisms	40%	Plants and autotrophic bacteria	40%	Radiative forcing
COS	Sulfur-reducing microorganisms in salt marshes and soils	21%	Plants and soil microorganisms	72%	Aerosol
Nonmethane VOCs	Plants	80%	Soil microorganisms	Negligible	Reacts with oxidized pollutants
CH_4	Methanogens	70%	Methanotrophs (nitrifiers)	10%	Radiative forcing
N_2O	Denitrifiers and nitrifiers	65%	Denitrifiers	Unknown	Radiative forcing and O_3 removal (stratosphere)
NO and NO_2	Denitrifiers, nitrifiers, and plants	40%	Denitrifiers and plants	Unknown	Photochemical smog
CO	Plants	5%	Soil microorganisms and plants	15%	O_3 formation (troposphere) and CH_4 destruction (stratosphere)

Shown are the gas species of interest, the organisms responsible for producing and consuming them, a rough estimate of the percentage of total annual production or consumption mediated by the terrestrial biosphere (e.g., of all global processes that consume COS each year, plants are estimated to consume 70%), and a brief description of the role of the gas species in atmospheric chemistry and climate.

climate, atmospheric composition, and land cover arising from human activities will likely continue to affect and be affected by ecosystem–atmosphere interactions.

In this section, we first explain the biophysical and physiological basis for water and energy interactions between terrestrial ecosystems and the atmosphere. We then examine some of the major ways in which global change affects ecosystem–atmosphere interactions. Much of our current understanding derives from atmospheric general circulation models (AGCMs), which have developed rapidly in recent years to include realistic parameterizations of the land surface, including the physiological responses of vegetation to multiple environmental factors. Although much uncertainty exists in the magnitude, and in some cases direction, of ecosystem–atmosphere interactions, modeling and large-scale experimental studies clearly indicate that the potential feedbacks are large.

The Biophysics and Physiology of Ecosystem–Atmosphere Interactions

The presence of vegetation affects a number of key land surface characteristics that are important determinants of the surface energy balance and the water and energy exchange with the atmosphere.

Albedo

Vegetation affects the reflectivity, or albedo, of the Earth's surface, the land surface parameter having the largest influence on the surface radiation budget. Albedo is the integrated reflectance over the solar spectrum (0.0–4.0 μm) and is lower for vegetation than bare soil (Table 2) because leaves absorb strongly in the visible wavelengths (0.4–0.7 μm) useful in photosynthesis and moderately from 0.7 to 4.0 μm . In contrast, soils have lower average absorption across the solar spectrum. Although leaves of different plant species vary somewhat in reflectivity, albedo is primarily sensitive to the leaf area index (LAI), the average amount of leaf area per ground area ($\text{m}^2 \text{m}^{-2}$). Values of LAI range from 0 for extreme deserts to one in arid regions and up to 5–7 or more for forests. The vegetation influence on albedo also varies temporally. For example, forest albedo generally increases in winter when deciduous trees are leafless or evergreens are snow covered, cropland and grassland albedo varies seasonally as the plant canopy develops and then senesces, and extreme events including droughts, pest outbreaks, and severe storms can reduce vegetation cover and increase albedo. Over longer time scales, the changing distribution of land surface albedo is closely tied to movement of vegetation zones in response to climate variation.

Table 2 Reflectivity (albedo) of various surfaces

Surface	Albedo
Forests	0.05–0.18
Grassland	0.22–0.28
Crops	0.15–0.26
Snow	0.75–0.95
Wet soil	0.09 ± 0.04
Dry soil	0.19 ± 0.06
Water	0.05 to >0.20

Sensible heat, latent heat, and evapotranspiration

Ecosystems have a major influence on how the net radiation received at the surface is balanced by losses of sensible and latent heat, which in turn have profound effects on weather and climate. Sensible heat flux from land warms the overlying air and planetary boundary layer. Latent heat is the energy required to evaporate water from soils and plants, and acts to cool the surface. Evaporated water can be transported above the planetary boundary layer, where it may release heat during condensation to form clouds (which affect radiation balance) or precipitation, often at considerable distance from the site of surface evaporation. The presence of vegetation generally increases latent heat flux relative to sensible heat flux. Of the 111 000 km^3 of precipitation on land each year, about 71 000 km^3 returns to the atmosphere by evaporation from soils and transpiration from plants (together considered 'evapotranspiration,' ET), the balance reentering the oceans as river flow. Globally, latent heat releases from the surface about three-quarters, and sensible heat one-quarter, of the annual average net radiation received by the surface.

The ratio of sensible to latent heat flux densities is known as the Bowen ratio (β). Average β varies inversely with water availability on land, ranging from about 0.2 for tropical rain forests to 0.4–0.8 in temperate forests and grasslands, 2–6 for semiarid regions, and 10 for deserts. The Bowen ratio is not static, however; distinct daily, seasonal, and annual trends arise from variation in LAI, soil and plant surface moisture availability, the surface–atmosphere vapor pressure deficit (VPD), and the resistance of the plant canopy to transpiration. Transpiration is the diffusion of water vapor along the concentration gradient from the saturated interior surfaces of leaves to the surrounding air via microscopic pores known as stomata

Figure 3 Schematic representation of exchange of water vapor (e), carbon dioxide (C), and heat by leaves. Gas flux rates are determined by the leaf-to-air concentration gradient and the combined stomatal and boundary layer resistance to diffusion. Light-dependent photosynthetic assimilation of CO_2 causes daytime $C_i < C_a$ and a net uptake of CO_2 by the leaf, while in the absence of light, leaf respiration causes $C_i > C_a$ and the net flux is from the leaf. Stomatal resistance is under physiological control and responds to light, temperature, humidity, and CO_2 concentration. Subscripts i, s, and a refer to interior, surface, and ambient, respectively. After Sellers, P.J., Dickinson, R.E., Randall, D.A., et al. 1997. Modeling the exchanges of energy, water, and carbon between continents and the atmosphere. *Science* 275, 502–509.

(Figure 3), and it is the plant process that most directly impacts ecosystem–atmosphere exchange of water and latent heat. Transpiration can enhance total surface evaporation because plants can extract water from below the soil surface, which itself develops high resistance with mild drying, and because plant canopies can present multiple layers ($LAI > 1$) for evaporation. An example of the importance of transpiration to water balance is apparent from figures for the Amazon basin estimating that up to 50% of regional precipitation arises from water transpired from plants elsewhere in the basin.

Stomata act as variable-aperture valves, the resistance (or conductance) of which responds to environmental factors including light, temperature, soil moisture, VPD, and CO_2 concentration. Canopy conductance is the stomatal conductance averaged over the total canopy leaf area. Because photosynthetic uptake of CO_2 by land plants shares the same stomatal diffusion pathway as transpiration, stomatal conductance simultaneously influences water, energy, and carbon fluxes. Theoretical studies suggest that stomatal conductance sometimes varies so as to optimize the efficiency of carbon gain relative to water loss. Conditions tending to enhance water stress to plants, particularly low soil moisture and high VPD, typically lead to partial stomatal closure, which then causes a decrease in transpiration and latent heat flux and an increase in surface temperature and sensible heat flux (i.e., β increases). The potential for ecosystem–atmosphere feedbacks mediated by stomatal physiology can be appreciated from the fact that stomatal conductance, through its control on transpiration and latent heat, can influence the conditions (e.g., VPD) to which it also responds. This is relevant in the context of global change because several global change factors (altered temperature, moisture availability, and CO_2) affect stomatal conductance and, thus, potentially can feedback to either amplify or moderate these changes.

Aerodynamic resistance

A third means by which ecosystems affect surface–atmosphere interactions is via their influence on the aerodynamic resistance of the land surface. Aerodynamic resistance varies inversely with wind speed and the log of the surface roughness length, the latter being about 10% of the vegetation height. Thus, for a given wind speed, taller vegetation such as forests has a lower aerodynamic resistance than shorter vegetation (e.g., grasslands), and promotes greater turbulent transfer of sensible and latent heat away from the surface. The vertical structure of the daytime atmospheric boundary layer is also highly dependent on partitioning of sensible and latent heat; a deeper boundary layer develops when sensible heat flux is large and convection increases.

Terrestrial ecosystems have several additional influences on land surface properties and processes. Vegetation shields soil from radiation inputs, reducing the magnitude of the components of the soil energy budget. Plant canopies also intercept precipitation, decreasing moisture reaching the soil and cooling the canopy surface when intercepted rain reevaporates. Finally, the distribution of roots in the soil profile affects the water available for ET. Studies of variation in the natural abundance of stable isotopic forms of water ($H_2^{18}O$ and $^2H^1HO$) in precipitation, groundwater, soils, plants, and the atmosphere are beginning to reveal the different sources of

water that is evaporated from soils or transpired by plants, and the importance of these atmospheric inputs to local and regional vapor pressure and precipitation.

Terrestrial Ecosystem Effects on Climate

The land surface parameters described in this article underlie influences of ecosystems on climate that are evident from observational and modeling studies. Sparsely vegetated urban areas feel warmer, and are warmer, than nearby forests or grasslands. In the north central United States, the rate of increase of mean surface temperature during spring slows abruptly as deciduous trees leaf out and increased latent heat flux imparts a cooling effect that counteracts the increasing insolation. The aridity of deserts is reinforced by their lack of vegetation, and, conversely, water transpired by tropical rain forests returns to these regions as precipitation. A variety of AGCMs have explored vegetation controls on climate for major regions of the terrestrial biosphere. Forest clearing for agriculture in the eastern and central United States during the 1800s is estimated to have resulted in cooler summers and autumns, consistent with the instrumental record. The cooling was due to changes in vegetation characteristics, in this case primarily reduced leaf area, which increased albedo, and reduced net radiation and sensible heating of the atmosphere. AGCM simulations that replaced Amazon forests with grassland estimated substantial reductions (300 mm year^{-1}) in ET and precipitation and increases in surface temperatures of $3\text{--}5^\circ\text{C}$. Changes in ET and precipitation arose from reduced LAI and decreased roughness length, which reduced turbulent transfer of moisture above the planetary boundary layer. Surface temperatures increased because latent heat flux decreased more (12 W m^{-2}) than did absorption of solar radiation (6 W m^{-2}), the latter due to increased albedo. Reduced ET following rainforest clearing is also predicted to decrease cloud cover, lessening the effect of increased surface albedo by increasing incident solar radiation, but also allowing more outgoing longwave radiation to be lost by the warmed land surface.

An AGCM scenario of replacing all boreal forests with bare ground or tundra (vegetation of short stature, with low leaf area vegetation) showed that boreal forests have a strong warming influence during winter and summer relative to the alternative cover situations. The warming results from the lower albedo of forests than snow, which is masked by the overlying trees. Under the deforestation scenario, land surfaces at high latitudes were up to 12°C colder in April, and remained as much as 5°C colder in July, when the albedo effect was small. These terrestrial changes were linked to sea surface conditions; the colder winter air temperature caused by deforestation reduced sea surface temperature (SST) in Arctic regions, inducing a thermal lag that inhibited warming of land surfaces in the summer. Lower SSTs increased the extent of sea ice, increasing ocean albedo and reinforcing the cooling effect of deforestation. These simulated effects of boreal deforestation were not limited to the boreal region itself; at latitudes as low as 30°N , simulated air temperatures were up to 3°C cooler throughout the year in the deforestation scenario compared to current, control conditions. These examples of ecosystem impacts on climate illustrate the

importance of including land cover change in models of future global climate.

Global Change and Ecosystem–Atmosphere Interactions

Global change, including changes in climate, atmospheric composition, and land use, will alter ecosystem–atmosphere interactions by changing the abundance, distribution, and functioning of different terrestrial ecosystems. For clarity, we discuss ecosystem responses and feedbacks to each of these major global changes separately, but recognize that these interactions are likely to be highly interdependent in the real world.

Climate change

Global climate change models project an increase in globally averaged temperature of 2.4–6.4 °C for the period 2090–2100 compared to 1980–99. The broad range of likely temperature increase is primarily due to uncertainty in projections of future greenhouse gas emissions by human activities. Temperature increases for terrestrial ecosystems should be greater than the global average because the land surface is not as thermally buffered as the oceans. High-latitude regions are very likely to warm considerably more than equatorial and midlatitudes (a phenomenon known as ‘polar amplification’) because warming will reduce the extent of snow and ice cover, decreasing albedo and increasing net radiation. Winter warming may exceed summer warming in high latitudes, while where soil moisture is low, summer warming may exceed winter warming because of low latent heat loss. Warming will drive greater ocean evaporation, and globally averaged precipitation is expected to increase by about 10%. Precipitation is likely to increase in high latitudes in winter as major storm tracks shift northward. At midlatitudes, precipitation is likely to increase in winter, with rain increasing relative to snow, but likely to decrease in summer in continental interiors. Aridity is likely to increase in currently arid regions because although increased surface temperatures will drive more evaporation, precipitation will decrease because the water-holding capacity of air increases nonlinearly with temperature according to the Clausius–Clapeyron relationship, and so air vapor pressure will tend to be farther from saturation. Most AGCM projections also forecast increased frequency of extreme weather events, including severe storms and droughts.

The primary approach to understanding climate-driven changes in vegetation distribution is based on current correlations between natural vegetation and climate, the so-called ‘equilibrium’ approach. The assumption is that, after climate changes, vegetation will reequilibrate according to the same relationship that currently exists. Thus, for example, as high latitudes warm, boreal forests will migrate northward and arctic tundra will be compressed into a narrower latitudinal band. Similarly, vegetation zones should shift upward in mountainous regions to track increases in temperature, a pattern of change that would reduce the extent and biodiversity of the uppermost, alpine tundra ecosystems. Zones of optimal grain production in North America may shift northward into Canada. In some continental regions, predictions are confounded by large uncertainties in precipitation

changes and the relative influence of increased temperature and altered precipitation in increasing or decreasing moisture stress to vegetation.

Although simple, an equilibrium approach is potentially misleading. Vegetation is unlikely to migrate rapidly enough to track the predicted pace of anthropogenic climate change, meaning there will be transient periods in which vegetation and climate are mismatched with respect to the equilibrium models. In addition, other determinants of future vegetation distribution, including herbivory, fire, severe storms, and human activities, can strongly affect vegetation composition, independent of the climate–vegetation correlation. In Australia, for example, fire frequency is expected to increase with climate change because of an increased probability of the high temperatures associated with ignition of bush fires. In the western United States, the frequency and severity of wildfires have increased as runoff from mountain snow occurs earlier, lengthening the potential fire season. Fire frequency and intensity may also be affected by changes in chemical properties of plant tissues produced in elevated CO₂. Outbreaks of insect herbivores are increasing in temperate and boreal forests, in part because milder winters increase insect survival, but their implications for local, regional, or global climate are yet to be explored. Given these complexities, coupled vegetation–AGCM models are increasingly including much transient, and in some cases nonlinear, behavior of vegetation distribution, behavior that can feedback to alter the pattern and pace of climate change.

Rising atmospheric CO₂

The stomatal response to CO₂ is critical to determining overall vegetation feedback to climate because it impacts latent and sensible heat exchange and return of water vapor to the atmosphere in transpiration. Experimental studies with a large number of plant species indicate that stomatal conductance is reduced by about 25% with a doubling of current atmospheric CO₂; there is considerable variation among species, with coniferous trees typically responding less than deciduous trees and herbaceous species typically showing the largest responses. The stomatal response to CO₂ can change over time as plant physiology adjusts to altered ecosystem biogeochemistry and the availability of essential resources, notably soil nitrogen. Whereas early AGCM studies addressed only the radiative effects of increased CO₂, current models specifically examine the role of vegetation physiology by allowing stomatal conductance and photosynthesis to respond to climatic conditions and atmospheric CO₂. Comparisons of AGCM simulations for the radiation-only (physical effects of CO₂) case to situations where vegetation physiology also responded in a realistic manner to increased CO₂ clearly illustrate the importance of vegetation feedbacks to the climate system. For tropical latitudes, the fully adjusted physiological response (reduced stomatal conductance) accounts for one-third of the nearly 3 °C increase in surface temperature. Global CO₂ assimilation by vegetation increased by 11–36% depending on the degree of physiological adjustment of levels of photosynthetic enzymes. Lesser increases in CO₂ assimilation and the larger increases in surface temperature come about when leaf nitrogen concentration, which is correlated with levels of photosynthetic

enzymes, decreases in elevated CO₂ and stomatal conductance declines strongly, consistent with maintenance of high photosynthetic water use efficiency. Thus, ecosystem biogeochemical responses, particularly components of the nitrogen cycle, can influence the response of water and energy exchanges to elevated CO₂.

Land cover and land use change

Ongoing human-caused changes in land use and land cover will undoubtedly impact biosphere–atmosphere interactions, water and energy exchanges being no exception. These impacts arise from the influence of key land surface parameters (roughness length, albedo, and LAI) on climate, as described in this article. Predictions of patterns of future land cover change carry substantial uncertainty, because land use depends on many different social and economic factors. It is safe to assume, however, that in tropical regions the trend toward increased conversion of forests to grasslands and croplands will continue. In the developed regions of the temperate zone, there has been a net increase in forested area in some regions as increased agricultural efficiency has allowed croplands to be abandoned and to convert back to forests. Increased rates of timber extraction in some regions such as Siberia may introduce climatic effects qualitatively similar to those estimated in simulations of extreme boreal deforestation. Retrospective studies of past, well-quantified patterns of conversion of natural vegetation to various agricultural conditions (pastures, crops, and associated irrigation) indicate that land cover change has been regionally important, but counteracting influences in tropical and temperate regions have probably caused little change in global temperature. In general, tropical forest conversion has warmed those regions, while temperate forest conversion has produced a cooling. This balance will likely not continue, however, because tropical deforestation has accelerated and temperate deforestation may be decelerating.

Summary and Conclusions

Together, the atmosphere and terrestrial biosphere form a coupled, interactive system, exchanging materials and energy in ways that critically regulate both biological and atmospheric processes (Figure 1). Biological production and consumption of greenhouse gases and aerosols influence the radiative balance of the atmosphere, while production and consumption of reactive gases affect atmospheric chemistry, including the formation and destruction of important pollutants. Similarly, plants mediate the partitioning of solar radiation incident on the terrestrial surface, partitioning that

affects regional and even global climate. Primarily mediated by plants and microorganisms, biosphere–atmosphere exchanges vary over the globe because of organisms' physiological and ecological responses to the environment. Ongoing, human-caused global changes are already altering biosphere–atmosphere exchanges, and these impacts are large enough that they could substantially shape the responses of the coupled biosphere–atmosphere system to future global changes. To better understand the consequences of anthropogenic global change, it will be critical to incorporate these complex interactions in AGCMs.

Synopsis

This article begins with a brief overview of the theory describing internal gravity wave structure, propagation, and influences in the atmosphere. Of particular relevance are the gravity wave characteristics that allow them to attain high altitudes and account for significant fluxes of energy and momentum. The dominant gravity wave sources are reviewed and the propagation of the resulting gravity waves through representative mean wind profiles is discussed. Also addressed are the dynamics that contribute to gravity wave spectral evolution, dissipation, turbulence generation, energy and momentum deposition, and the constraints imposed by these dynamics on the character of the gravity wave wave number spectra with increasing altitude. We conclude with a brief overview of the primary gravity wave influences on the mean circulation and structure of the atmosphere.

Introduction

The middle atmosphere refers to regions of the atmosphere extending from the tropopause (e.g., the top of the troposphere at $\sim 10\text{--}16$ km) to the homopause (an altitude of ~ 110 km, below which the atmosphere remains relatively well mixed). It includes (1) the stratosphere, extending from the tropopause to the stratopause at ~ 50 km in which mean temperature increases with altitude, (2) the mesosphere, extending from the stratopause to the mesopause (which varies in altitude between ~ 87 and 100 km) in which mean temperature decreases with altitude, and (3) the lower thermosphere above the mesopause in which mean temperature again increases with altitude. Radiative processes are largely responsible for the increasing temperatures with altitude in the stratosphere and thermosphere. In the mesosphere, however, dynamical mixing and transport processes contribute to the decrease of mean temperature with altitude. The mean state of the middle atmosphere is stably stratified and in approximate hydrostatic balance at all altitudes, and the corresponding mean density decreases approximately exponentially with increasing altitude. Stable stratification enables vertical wave propagation and decreasing mean

density causes wave amplitudes to increase dramatically with increasing altitude. Those waves for which gravity and stable stratification are the dominant influences are referred to as gravity waves.

Gravity waves play key roles in middle atmosphere dynamics for several reasons. They are ubiquitous throughout the atmosphere, arising in response to a variety of sources in the troposphere and middle atmosphere. Because they increase in amplitude as they propagate vertically, they dominate the motion spectrum at small and intermediate spatial and temporal scales (from a few to hundreds or thousands of kilometers and from minutes to tens of hours). More importantly for the middle atmosphere, they propagate readily over large distances and depths, account for substantial fluxes of energy and momentum, and experience filtering and dissipation due to interactions with the environments through which they propagate. The flux divergences arising from gravity wave dissipation, in particular, result in significant forcing of the large-scale circulation and the thermal and constituent structures of the middle atmosphere.

The goal here is to provide a brief survey of the theory describing gravity wave propagation and effects, the significant sources of gravity waves in the lower and middle atmosphere,

the factors influencing their evolution with increasing altitude, and their various roles in middle atmosphere dynamics.

Theory

Gravity waves are a subset of more general atmospheric motions that are described by equations expressing conservation of momentum, mass, and energy for a fluid system. These equations, known as the Navier–Stokes equations, are nonlinear, time dependent, dissipative, and have no general analytic solutions. We can gain significant insights into the structure and behavior of gravity waves, however, by seeking approximate solutions for linear waves in idealized environments.

Perturbation Equations

Making approximations that eliminate both acoustic and planetary wave solutions, the linear, inviscid equations describing gravity wave perturbations in a hydrostatic mean state with mean horizontal velocity $(\bar{u}, \bar{v})$ may be written as

$$du'/dt + w'\partial\bar{u}/\partial z + fu' + (1/\bar{\rho})\partial p'/\partial x = 0 \quad [1]$$

$$dv'/dt + w'\partial\bar{v}/\partial z + fv + (1/\bar{\rho})\partial p'/\partial y = 0 \quad [2]$$

$$dw'/dt + (1/\bar{\rho})\partial p'/\partial z - g\theta'/\bar{\theta} = 0 \quad [3]$$

$$d\theta'/dt + w'\partial\bar{\theta}/\partial z = 0 \quad [4]$$

$$\partial u'/\partial x + \partial v'/\partial y + (1/\bar{\rho})\partial(\bar{\rho}w')/\partial z = 0 \quad [5]$$

In these equations, u' , v' , w' , p' , and θ' are the perturbation zonal, meridional, and vertical velocities, pressure, and potential temperature; $\bar{\rho}$ and $\bar{\theta}$ are the mean density and potential temperature, respectively; $f = 2\Omega \sin \phi$ is the Coriolis parameter, with Ω the rotational frequency of the Earth and ϕ the latitude; and $d/dt = \partial/\partial t + \bar{u}\partial/\partial x + \bar{v}\partial/\partial y$ is an advective derivative.

Potential temperature is a conserved quantity for adiabatic (energy conserving) motions and is equal to the temperature of an air parcel restored adiabatically to a reference surface pressure. The static stability of the mean state (a measure of the degree of stratification of the atmosphere) may be expressed in terms of mean temperature or potential temperature as eqn [6], where g is the gravitational acceleration, $\bar{T}$ is the temperature, and C_p is the specific heat of air at constant pressure.

$$N^2 = (g/\bar{\theta})\partial\bar{\theta}/\partial z = (g/\bar{T})(g/C_p + \partial\bar{T}/\partial z) \quad [6]$$

The quantity N is the buoyancy frequency (see **Gravity Waves: Buoyancy and Buoyancy Waves: Optical Observations; Buoyancy and Buoyancy Waves: Theory**), which is the natural frequency of oscillation for an air parcel displaced vertically from its equilibrium altitude. We see from eqn [6] that N is larger (smaller) where temperature increases (decreases) with altitude. Thus, the stratosphere and lower thermosphere are more stratified than (and have higher static stability than) the troposphere and mesosphere.

To a good approximation, the atmospheric density varies as shown in eqn [7], where $H = R\bar{T}/g$ and R is the gas constant.

$$\bar{\rho}(z) = \rho_0 e^{-z/H} \quad [7]$$

For typical temperatures in the middle atmosphere, $H \approx 7$ km, so that mean density decreases by $\sim 10^6$ from the tropopause to the mesopause (~ 90 km).

In order to provide the simplest insights into gravity wave structure, we assume, for now, that the mean shear terms in eqns [1] and [2] may be neglected and that N^2 is constant, and seek solutions for u' having the form of eqn [8], with similar forms for other perturbation quantities.

$$u' = u_0 e^{z/2H} e^{i(kx + ly + mz - \omega t)} \quad [8]$$

These perturbations comprise solutions with wave number components (k, l, m) and a ground-based frequency ω . The exponential growth term in the perturbation results from the mean density decrease with altitude and implies that even small-amplitude waves may achieve appreciable amplitudes and effects at greater altitudes. Substitution into eqns [1]–[5] yields a set of algebraic equations for $(u', v', w', \theta', p')$ that can be combined to form a dispersion relation given by eqn [9].

$$m^2 = (k^2 + l^2)(N^2 - \omega_i^2)/(\omega_i^2 - f^2) - 1/4H^2 \quad [9]$$

Here, $\omega_i = \omega - k\bar{u} - l\bar{v}$ is the intrinsic frequency, or frequency of the gravity wave relative to the mean motion $(\bar{u}, \bar{v})$. The dispersion relation shown in eqn [9] relates the wave intrinsic frequency to the wave spatial structure (k, l, m) , mean atmospheric stability N , Coriolis parameter f , and density scale height H .

For illustration, we further assume that gravity wave propagation is in the zonal direction such that $l = 0$ and that the vertical wavelength, $\lambda_z = 2\pi/m \ll 4\pi H$, such that the last term in eqn [9] is negligible. Then the polarization relations that relate the various perturbation quantities can be expressed as in eqns [10]–[13].

$$v' = -ifu'/\omega_i \quad [10]$$

$$w' = -ku'/m \quad [11]$$

$$\theta'/\bar{\theta} = -iN^2 w'/\omega_i g = ikN^2 u'/m\omega_i g \quad [12]$$

$$p'/\bar{p} = -(N^2 - \omega_i^2)w'/m\omega_i = k(N^2 - \omega_i^2)u'/m^2\omega_i \quad [13]$$

The dispersion relation, eqn [9], reveals that gravity waves propagate vertically (with real m) only for $f < \omega_i < N$. For $\omega_i > N$, or more generally for $m^2 < 0$ owing to the last term in eqn [9], m is imaginary and gravity wave motions decay exponentially with altitude. Within the range where vertical propagation occurs, however, a wide range of wave motions is possible. For gravity waves with $\omega_i \sim f$ (called inertia-gravity waves), horizontal motions are ellipses with a major to minor axis ratio of ω_i/f , vertical motions are suppressed, $m^2 \gg k^2 + l^2$ (i.e., horizontal wavelengths are much larger than vertical wavelengths), pressure perturbations are negligible, and the dispersion relation takes the form of eqn [14], where $k_h = (k^2 + l^2)^{1/2}$ is the horizontal wave number in the direction of propagation.

$$m^2 = k_h^2 N^2 / (\omega_i^2 - f^2) \quad \text{or} \quad \omega_i^2 = k_h^2 N^2 / m^2 + f^2 \quad [14]$$

At the opposite extreme, with $\omega_i \sim N$, either large k_h (small horizontal wavelength, $\lambda_h = 2\pi/k_h$) or mean atmospheric density variations (the $1/4H^2$ term in eqn [9]) can result in gravity waves having large vertical wavelengths, $\lambda_z = 2\pi/m$, and large vertical motions, and the appropriate dispersion relation is given by eqn [15].

$$m^2 = k_h^2 N^2 / \omega_i^2 - k_h^2 - 1/4H^2 \quad [15]$$

For gravity waves having intermediate intrinsic frequencies, $f^2 \ll \omega_i^2 \ll N^2$ (describing a large fraction of relevant gravity waves), transverse motions are negligible ($v' \sim 0$), motions are largely in a vertical plane, vertical motions are larger than for inertia-gravity waves, and gravity waves easily propagate vertically. In this case, the dispersion relation (eqn [16]) is especially simple and insightful.

$$m^2 = k_h^2 N^2 / \omega_i^2 \quad [16]$$

This yields an intrinsic frequency given by eqn [17], where ϕ is the angle of the gravity wave phase surfaces from the horizontal.

$$\omega_i = \pm k_h N / m = N \sin \phi \quad [17]$$

We now return to the influences of mean wind shear that were neglected above to allow a simple and insightful derivation of the dispersion and polarization relations. Influences of mean wind shear need to be included in more general assessments of gravity wave behavior because the large majority of gravity waves arising in the lower atmosphere and influencing the middle atmosphere have phase velocities within the range of large-scale winds (including mean, tidal, and planetary wave winds) in the lower and middle atmosphere. Writing the component of the mean wind $(\bar{u}, \bar{v})$ in the direction of gravity wave propagation as $\bar{u}_h(z)$, the ground-based and intrinsic frequencies may be written as $\omega = k_h c$ and $\omega_i = k_h (c - \bar{u}_h(z)) = k_h c_i(z)$, respectively (where c_i is the intrinsic phase speed along the direction of gravity wave propagation). For intermediate-frequency gravity waves, eqn [16] may then be written as eqn [18].

$$m(z) = \pm N / (c - \bar{u}_h(z)) = \pm N / c_i(z) \quad \text{or} \quad \lambda_z(z) = 2\pi c_i(z) / N \quad [18]$$

Thus, m and λ_z are now functions of z that are simply related to the atmospheric stability, N , and the variable intrinsic gravity wave phase speed, c_i , due to mean wind variations in altitude.

Wind shear and curvature also have implications for gravity wave structure and propagation that require a more general dispersion relation for mid- and high-frequency gravity waves accounting for variable $\bar{u}_h(z)$ and displayed as eqn [19].

$$m^2 = k_h^2 N^2 / \omega_i^2 - k_h \bar{u}_z / \omega_i H + k_h \bar{u}_{zz} / \omega_i - k_h^2 - 1/4H^2 \quad [19]$$

This dispersion relation differs from that in eqn [15] by inclusion of shear and curvature terms, where $\bar{u}_z(z)$ and $\bar{u}_{zz}(z)$ are the first and second derivatives of $\bar{u}_h(z)$ in the vertical, and by allowing all quantities except k_h to now vary in z . Variable mean wind in altitude along the gravity wave propagation direction allows two limiting cases of special interest because of

their impacts on gravity wave structure and propagation. One occurs where ω_i approaches zero, termed a critical level with $c_i(z) = 0$. The behavior of the solution in the vicinity of a critical level at $z = z_0$ in a linear mean wind shear, $\bar{u}_h(z) = U_z(z - z_0)$, is obtained as the lowest order term in a Frobenius series expansion and has the form given by eqn [20].

$$w'(z) \sim \delta z^{1/2} e^{\pm i\mu \delta z} \quad [20]$$

Here, $\delta z = z - z_0$, $\mu = (\text{Ri} - 1/4)^{1/2}$, and $\text{Ri} = N^2 / U_z^2 > 1/4$ for stability. Equations [11] and [20] imply $u'_h(z) \sim \delta z^{-1/2} e^{\pm i\mu \delta z}$ such that the gravity wave vertical flux of horizontal momentum (see below), $\bar{\rho} u'_h w' / 2$ is constant with altitude for conservative wave propagation.

The steady-state critical-level gravity wave structure inferred above is singular and implies strong gravity wave attenuation for realistic propagation environments having $\text{Ri} \gg 1/4$. It also implies strong potential roles for viscosity, nonlinearity, and transient effects, all of which have been found to contribute to gravity wave instability and/or dissipation in such regions. Indeed, these various processes typically play significant roles in constraining gravity wave amplitudes before a critical level is approached, causing a critical level to be a very effective barrier to continued vertical propagation of the incident gravity wave.

A second barrier to upward gravity wave propagation occurs where increasing c_i (or ω_i) and/or decreasing $N(z)$ with increasing altitude in eqn [19] results in $m^2 = 0$, termed a turning level, above which the gravity wave is evanescent ($m^2 < 0$), resulting in vertical reflection. More generally, variable mean winds and atmospheric stability can yield a layer within which a gravity wave has $m^2 > 0$ and propagating character, but above and below which $m^2 < 0$ and the gravity wave is evanescent. Such a layer is termed a duct and the gravity wave is termed a ducted gravity wave. It remains effectively trapped within the duct until the environment changes, or the gravity wave is dissipated, tunnels through an evanescent layer to another region of vertical propagation, or transfers energy to other motions via nonlinear interactions that may or may not be ducted. A final effect of mean winds on gravity wave propagation seen in eqn [19] is the new curvature term, $k_h \bar{u}_{zz} / \omega_i$, which, for $c_i > 0$ or $c > \bar{u}_h(z)$, causes a reduction in m^2 in the duct with $\bar{u}_{zz}(z) < 0$, where $k_h^2 N^2 / \omega_i^2$ is maximum because of small $c_i > 0$.

Ray paths in the plane of gravity wave propagation depicting the various gravity wave responses to a mean shear layer, including critical level absorption, reflection at a turning level, and refraction to larger and smaller intrinsic phase speeds (or frequencies) in an environment with constant $N(z)$ are illustrated in Figure 1. For illustration, we assume $|\omega_i| = |k_h N / m| = N |\sin \phi|$ is constant for all cases. Thus, all gravity waves have the same initial frequency, but varying intrinsic frequency, wavelength ratio, and vertical wavelength after encountering the shear layer. In Figure 1, ray path origins denote initial phase speeds relative to the mean wind. Gravity waves propagating to the right (along the mean wind) experience decreasing $|\omega_i|$ and phase slopes, those propagating to the left experience increasing $|\omega_i|$ and phase slopes. Smaller initial phase speeds are more susceptible to refraction. Dashed ray paths denote gravity waves that are prevented from propagating to higher altitudes due to either a critical level or a turning level, occurring where $\omega_i = 0$ or $m^2 = 0$ ($\omega_i \sim N$), respectively.

Figure 1 Ray paths for gravity waves having common initial intrinsic frequencies $\omega_i = N/1.4$, but different phase speeds and directions of propagation, encountering a mean wind shear. Solid lines denote gravity waves and phase structures that are refracted to higher (left) and lower (right) intrinsic frequencies. Dashed lines denote gravity waves that encounter a turning level (left) or critical level (right) due to more severe refraction accompanying smaller initial phase speeds.

The ray paths shown in **Figure 1** lead naturally to a discussion of gravity wave group velocity. This is the velocity at which a gravity wave packet propagates and transports energy and momentum. The group velocity components for medium and high-frequency gravity waves in the plane of wave propagation derived from [eqn \[19\]](#), assuming mean wind shear and curvature are small, are shown in [eqn \[21\]](#).

$$(c_{gh}, c_{gz}) = (\partial\omega/\partial k_h, \partial\omega/\partial m) = (\bar{u}_h, 0) + [k_h(N^2 - \omega_i^2), -m\omega_i^2] / [\omega_i(k_h^2 + m^2 + 1/4H^2)] \quad [21]$$

[Equation \[21\]](#) illustrates the two limiting cases for gravity wave vertical propagation nicely. For both a critical level and a turning level, [eqn \[21\]](#) implies (c_{gh}, c_{gz}) approaches $(\bar{u}_h, 0)$ and the gravity wave ceases to propagate vertically. For intermediate-frequency gravity waves for which $f^2 \ll \omega_i^2 \ll N^2$, [eqn \[21\]](#) reduces to [eqn \[22\]](#) below.

$$(c_{gh}, c_{gz}) = (\bar{u}_h, 0) + (\omega_i/k_h, -\omega_i/m) \quad [22]$$

Thus, for most gravity waves of importance in the middle atmosphere, the horizontal group velocity is the same as the horizontal phase speed, but the opposite progression in the vertical. Except for cases for which $\bar{u}_h(z)/c < -1$, downward phase progression implies upward gravity wave propagation and energy and momentum transport. This also implies that for upward gravity wave propagation, having c_i and $\omega_i > 0$, $c_{gz} = -\omega_i/m > 0$ and $m < 0$.

Low-frequency gravity waves are also described by the dispersion relation in [eqn \[9\]](#) for intrinsic frequencies $\omega_i^2 \ll N^2$ and $m^2 \gg 1/4H^2$ yielding the approximate relation in [eqn \[23\]](#).

$$\omega_i^2 = N^2 k_h^2 / m^2 + f^2 \quad [23]$$

The group velocity for low-frequency gravity waves is nearly horizontal, with the ratio of components $|c_{gz}/c_{gh}| = |k_h/m| = (\omega_i^2 - f^2)^{1/2}/N$. As a result, these gravity waves can propagate very large distances horizontally. While their vertical propagation is very slow, they nevertheless often comprise a large fraction of the total gravity wave kinetic and

potential energy and contribute to the environments through which intermediate- and high-frequency gravity waves propagate.

Gravity wave structure, refraction by mean winds, and amplitude growth with altitude noted above imply significant effects where amplitudes become large. Exponential amplitude growth with altitude enables even very small-amplitude gravity waves to achieve large amplitudes at high altitudes. The polarization relations imply that gravity wave propagation provides energy and momentum transport due to the fluxes arising from the gravity wave velocity and pressure fluctuations, the effects of which also grow exponentially with altitude. Of these fluxes, the vertical transport of horizontal momentum plays the dominant role, effectively transporting horizontal momentum in the direction of gravity wave propagation from the gravity wave source to the region in which the wave is dissipated. Other correlations arise accompanying mean density variations, compressibility, and dissipation, but these will not be addressed here. Finally, amplitude growth with increasing altitude ultimately yields sufficiently large gravity wave amplitudes, and momentum fluxes, to initiate a spectrum of instabilities. These various instabilities extract energy from the gravity wave, reducing its amplitude and momentum flux, thus causing a momentum flux divergence that acts as a local body force on the mean flow.

Considering first the effects of amplitude growth, a conservative gravity wave will experience an amplitude growth of $\sim e^{z/2H}$ according to [eqn \[8\]](#). In reality, however, dissipation and interactions occur at all altitudes and affect all gravity waves, hence the observed growth in gravity wave variances is less than half the conservative rate, with a ‘variance’ scale height $H_E \approx 2.3H$ throughout the lower and middle atmosphere. A growing gravity wave ultimately reaches an amplitude above which the atmosphere becomes locally ‘convectively unstable,’ having an inverted potential temperature gradient due to relative advection along slanted gravity wave phase lines. This condition may be written in terms of the gravity wave variables as in [eqn \[24\]](#).

$$(\partial\theta'/\partial z)_{\min} < -\partial\bar{\theta}/\partial z \quad \text{or} \quad |u'_h|_{\max} > c_i \quad [24]$$

In principle, gravity waves can succumb to instabilities at significantly smaller amplitudes, as all gravity waves at all amplitudes are unstable. Equation [24] nevertheless provides a useful guide for the likely occurrence of instability because instabilities typically progress much more rapidly at larger amplitudes. The consequence of instability is a reduction of the gravity wave amplitude to a value often much smaller (by 30% or more) than the nondimensional amplitude defined by the ratio of terms in eqn [24], e.g., $a = |u'_h|_{\max}/c_i > 1$, where $a = 1$ corresponds to incipient overturning and will be referred to hereafter as the 'breaking' amplitude near which instabilities become more likely. Equation [24] and the linear gravity wave structure near a critical level reinforce the expectation that critical level approach also yields gravity wave instability and dissipation. Given the impacts of instability on gravity wave amplitudes, propagation, and the environments in which they propagate, the mean state responses, and the character and effects of instabilities will be addressed in greater detail in the following sections.

Mean State Equations

The role of gravity waves in forcing the mean circulation and thermal structure of the middle atmosphere can be understood by examining the zonally averaged momentum and continuity equations. Assuming for simplicity a steady mean flow with negligible vertical shear, the appropriate equations are eqns [25] and [26] with a mean meridional and vertical (or residual) circulation, $(\bar{v}^*, \bar{w}^*)$, satisfying eqn [27].

$$-f\bar{v}^* = -(1/\bar{\rho})\partial F_x/\partial z = D_{F_x} \quad [25]$$

$$f\bar{u} + (1/\bar{\rho})\partial \bar{p}/\partial y = -(1/\bar{\rho})\partial F_y/\partial z = D_{F_y} \quad [26]$$

$$\partial \bar{v}^*/\partial y + (1/\bar{\rho})\partial (\bar{\rho} \bar{w}^*)/\partial z = 0 \quad [27]$$

Here, the asterisks denote the transformed Eulerian mean circulation, which expresses the net effects of wave forcing, and (F_x, F_y) is given by eqn [28] for a gravity wave having arbitrary propagation direction and intrinsic frequency ω_i .

$$(F_x, F_y) = \bar{\rho}(\overline{u'w'}, \overline{v'w'}) (1 - f^2/\omega_i^2) \quad [28]$$

For a gravity wave propagating upward and eastward relative to the mean flow (i.e., $c_{gz} > 0$, $c_{pz} < 0$, $k > 0$, and $c_i > 0$), we see from eqns [22] and [11] that $m < 0$ and $\overline{u'w'} > 0$. The terms (F_x, F_y) represent the mean vertical fluxes of horizontal momentum by gravity waves in the zonal and meridional directions. Momentum fluxes are nondivergent for conservative wave motions but are generally divergent when wave dissipation occurs. In the absence of wave dissipation, the solution to eqns [25] and [27] is a geostrophically balanced zonal mean flow with $(\bar{v}^*, \bar{w}^*) = 0$ and $\bar{u} = -(1/\bar{\rho}f)\partial \bar{p}/\partial y$. Momentum flux divergences arising from wave instability or filtering processes, on the other hand, lead to significant departures from a geostrophic mean flow and to a wave-driven residual circulation and thermal structure exhibiting large departures from radiative equilibrium.

Gravity Wave Sources

Two major gravity wave sources in the troposphere are believed to be topography and convection. Airflow over mountains leads to vertical displacements dictated by the terrain height and horizontal scale at zero phase speed relative to the ground. For horizontal wavelengths of ~ 10 km or longer, the vertical wavelength is determined by eqn [16] with $c = 0$: $\lambda_z \sim 2\pi \bar{u}_h(z)$. Mountain waves are prevented from reaching high altitudes by mean winds that cause critical levels near $\bar{u}_h(z) = 0$, such as occurs for nearly zonal propagation at middle and high latitudes in summer, or at low latitudes due to wind reversals in the stratosphere accompanying the quasi-biennial oscillation. In winter, however, sustained eastward winds extending into the mesosphere provide a propagation channel for the larger mountain wave horizontal wavelengths having largely zonal propagation and $m^2 > 0$. In such cases, these waves can reach the mesosphere or lower thermosphere, depending on the mean wind and tidal environment at those altitudes. Two examples of mountain waves seen by the Atmospheric Infrared Sounder (AIRS) on the Aqua satellite at ~ 41 km and one seen in the OH airglow at ~ 87 km are shown in the upper two and lower left panels of Figure 2.

Convection excites gravity waves by vertical motions within clouds, through buoyancy driven by latent heating, or by airflow over clouds in a sheared environment. The scales and frequencies of gravity waves that arise are dictated by the geometry and timescale of the convection. Shallow, broad convection excites primarily lower frequency gravity waves at smaller vertical scales; deep, narrow convection excites higher frequency gravity waves having larger vertical scales and vertical group velocities. Additionally, cloud complexes may act collectively as gravity wave sources on much larger spatial scales. Convection thus excites gravity waves spanning a wide range of scales and phase speeds. Deep and fast convective gravity waves (those having large vertical scales and relatively small horizontal scales, approximately tens to hundreds of kilometers) have sufficiently large horizontal phase speeds to often penetrate well into the mesosphere and thermosphere. An example of concentric gravity waves seen in OH airglow at ~ 87 km excited by deep convection and propagating through a weak mean wind environment at lower altitudes is shown in the lower right panel of Figure 2.

At greater altitudes, jet streams excite gravity waves through a process known as spontaneous imbalance through which an unbalanced flow achieves a new balanced state and conserves energy via gravity wave emission. The initial unbalanced flows are typically relatively shallow and broad (approximately 10 km deep and hundreds of kilometers across the jet stream), resulting in gravity waves having large horizontal scales, near-inertial frequencies, and small vertical group velocities. Such waves comprise the most energetic part of the gravity wave frequency spectrum in the stratosphere and mesosphere, but often propagate several thousand kilometers horizontally before reaching these higher altitudes. Unstable jet stream shear flows, often enhanced by inertia-gravity waves, also excite gravity waves through a process called envelope radiation, in which gravity wave scales are imposed by the event scale rather than by the detailed dynamics of shear instability itself.

Figure 2 Apparent mountain waves seen in AIRS temperatures at 2 hPa (~ 41 km) over New Zealand and Tasmania on 6–7 July 2011 (a and b; courtesy of Eckermann, S.D. (unpublished)) and in the OH airglow layer (~ 87 km) over the Andes centered at $\sim 32^\circ$ S on 3 July 2009 (c; courtesy of Smith, S., Baumgardner, J., Mendillo, M., 2009. Evidence of mesospheric gravity-waves generated by orographic forcing in the troposphere. *J. Geophys. Res.* 36, L08807. doi:10.1029/2008GL036936.). Shown in (d; courtesy of Yue, J.) are convective gravity waves due to deep convection over Northeast Colorado seen in OH airglow (~ 87 km) at a time of light mean winds.

Additional gravity wave sources at higher altitudes accompany gravity wave amplitude growth with altitude. As noted above, amplitude growth enhances the growth rates for wave-wave interactions and local shear- and buoyancy-driven instabilities. Both processes lead directly to excitation of additional gravity waves at scales defined by the specific wave-wave interactions or local instability dynamics. Local body forcing due to momentum flux divergence arising from localized instabilities and dissipation also generate what are called secondary gravity waves. Secondary gravity waves have scales imposed by the geometry of the forcing, allowing them to often have significantly larger scales, and higher propagation altitudes, than the primary gravity wave. Evidence for these additional gravity wave sources has been provided largely by numerical studies to date.

Spectra and Evolution with Altitude

Near major sources in the troposphere, the spectrum of gravity waves is determined largely by the source characteristics. But as altitude increases, the spectrum is shaped increasingly by other factors. Contributions from various sources necessarily broaden the spectrum, with topography, convection, jet streams, wind shears, and other sources at higher altitudes

typically contributing very different spatial scales, horizontal phase speeds, and intrinsic frequencies. Thereafter, variations in mean winds cause intrinsic frequencies and corresponding vertical wavelengths to also vary considerably with altitude. An illustration of gravity wave propagation for a mountain wave (with $c = 0$) and two convective gravity waves having equal and opposite zonal phase speeds in an idealized midlatitude summer zonal wind profile is provided in the left panel of Figure 3. For the convective gravity wave having $c > \bar{u}(z)$ on the right, increasing c_i above the eastward wind maximum at lower altitudes increases λ_z , accelerates vertical propagation, and enables the gravity wave to penetrate to much higher altitudes. Those gravity waves with $c = 0$ and $c < 0$, however, encounter critical levels where $c = \bar{u}(z)$ and are dissipated by viscosity or instability processes below this altitude. Hence, gravity wave propagation in mean wind shear redistributes wave energy in vertical wave number and removes those components of the spectrum that encounter critical levels within this altitude range. Additional spectral transfers accompany pervasive wave-wave interactions that act throughout the atmosphere.

The approximate constraints placed on gravity wave amplitudes described by eqn [24] imply what is termed ‘saturation’ of the gravity wave spectrum, which imposes an approximately universal spectral character where these dynamics occur. This

Figure 3 Gravity wave vertical wavelength dependence (left panel) on $c_i = c - \bar{u}_h(z)$ for a mountain wave having $c = 0$ and two convective gravity waves with westward ($c < 0$, left) and eastward ($c > 0$, right) phase speeds in a summer midlatitude zonal wind. Evolution of the vertical wave number spectrum of horizontal velocity variance $E_v(m)$ with altitude (right panel). The slope at large m is due to the constraint on wave amplitudes imposed by gravity wave saturation processes, allowing variance increases only at smaller m and causing a reduction in the characteristic vertical wavelength, m^* , with altitude. Induced diffusion and PSI in variable wind environments account largely for the transfer energy to smaller vertical scales.

‘saturated’ spectrum has a form and amplitude at large m given approximately by $E_v(m) \approx N^2/6m^s$, with $s \sim 2.5$ – 3 suggested by multiple observations. Instabilities and dissipation occur preferentially at smaller vertical wavelengths because these gravity waves are more easily Doppler shifted toward smaller $|c_i|$ by changing mean winds. Gravity waves at larger vertical wavelengths tend to be excited at much smaller initial amplitudes, have larger phase speeds so are less influenced by mean winds, grow approximately conservatively with altitude, and typically propagate to significantly higher altitudes before they attain sufficiently large amplitudes to participate in saturation processes. Wave–wave interactions, studied extensively in both oceanic and atmospheric contexts, likewise act to shape the gravity wave wave number and frequency spectra.

These various dynamics lead to a vertical wave number spectrum of horizontal velocity having an approximate form and amplitude given by $E_v(m) \approx N^2\mu/6(1 + \mu^4)$, where $\mu = m/m^*$ and m^* is a characteristic vertical wave number that decreases with altitude. Approximately conservative gravity wave propagation at small m yields a corresponding growth of total gravity wave kinetic energy (per unit mass) with a scale height $H_E \sim 2.3H$, as noted above. This approximate spectral form, and its evolution with altitude (for which there is now considerable observational and theoretical evidence), is illustrated in the right panel of Figure 3. The growth of horizontal kinetic energy with altitude occurs largely at $m < m^*$ and equates to an increase of ~ 100 between the tropopause and the mesopause and a corresponding increase of m^* by ~ 10 over this same altitude range. Characteristic vertical wavelengths are typically ~ 1 – 3 km in the lower stratosphere and

~ 10 – 30 km near the mesopause, with a similar increase in the magnitude of horizontal velocities (i.e., from ~ 3 m s $^{-1}$ at lower altitudes to ~ 30 m s $^{-1}$ near the mesopause). Despite the growth with altitude of gravity wave vertical wavelengths and amplitudes, the kinetic energy (per unit volume) decreases by $\sim 10^3$ between the tropopause and mesopause, implying that the large majority of gravity wave energy does not propagate to high altitudes, but rather contributes to instabilities, turbulence, mixing, and transport throughout the lower and middle atmosphere.

Also observed are ground-based and intrinsic frequency spectra, and airborne horizontal wave number spectra, of horizontal winds (and temperatures) that vary as $E_u(\omega) \sim \omega^p$ and $E_u(k_h) \sim k_h^p$ where $p \sim -5/3$, with corresponding frequency spectra of vertical velocities having the form $E_w(\omega) \sim \omega^{p+2}$ (except near f and N) under light wind conditions for which Doppler shifting effects are small. These frequency spectra imply that the major contributions to gravity wave momentum flux occur for the highest frequency gravity waves, with periods $T_{GW} < 1$ h contributing the dominant momentum fluxes at most altitudes.

Instability Dynamics

As noted above, there is a broad spectrum of instabilities that cause energy exchanges among various modes and/or gravity wave dissipation, amplitude reductions, mixing and transport, and energy and momentum flux divergence. Resonant and off-resonant wave–wave interactions transfer energy to gravity

waves having different frequencies and wave numbers than the parent gravity wave(s), but typically without explicit dissipation. Local instabilities also exhibit many forms, depending on gravity wave frequency, amplitude, spatial localization, and environment. Collectively, these interactions and instabilities are responsible for the approximately universal character of the gravity wave spectrum in the atmosphere, and its analog in the oceans. Indeed, approximate descriptions of these various dynamics underlie all parameterization schemes intended to describe gravity wave propagation, spectral evolution, energy and momentum transport and deposition, and their influences throughout the atmosphere.

Resonant wave-wave interactions comprise triad interactions satisfying conditions given by eqn [29].

$$\mathbf{k} = \mathbf{k}_1 + \mathbf{k}_2 \quad \text{and} \quad \omega_i = \omega_{i1} + \omega_{i2} \quad [29]$$

Here, $\mathbf{k}$ and ω_i denote the primary gravity wave's wave number vector and intrinsic frequency, and subscripts denote these quantities for secondary gravity waves arising from these interactions. There are three primary classes of interactions having different character. These include (1) elastic scattering, (2) induced diffusion, and (3) parametric subharmonic instability (PSI). Each class has unique characteristics. Elastic scattering refers to the backscatter of an upward propagating gravity wave into a downward propagating gravity wave (or vice versa) of comparable vertical wave number by a low-frequency gravity wave (or mean motion) having twice the vertical wave number (i.e., Bragg scattering). Induced diffusion amounts to a transfer of energy from one gravity wave to another that has an almost identical wave number via interaction with a low-frequency gravity wave (or mean motion) having a much smaller vertical wave number (i.e., analogous to refraction of a gravity wave packet in a large-scale shear flow). Finally, PSI refers most often to the exchange of energy between a primary gravity wave of intermediate frequency and two secondary gravity waves having approximately half the primary gravity wave frequency and nearly opposite (and more nearly vertical) wave numbers. Of these interactions, PSI plays the major role at low frequencies and high wave numbers, and induced diffusion dominates energy transfers at high frequencies and high wave numbers. Wave-wave interactions are weaker (hence gravity wave propagation is more nearly linear) at low frequencies and low wave numbers, $m < m^*$, where gravity wave amplitudes are below their saturated values and grow strongly with increasing altitude.

Higher-order, off-resonant interactions can also occur, particularly in cases in which gravity waves having significant amplitudes and different characters are superposed. In such cases, mutual deformation of the velocity fields leads to rapid energy transfers and additional gravity wave excitation. Collectively, these various wave-wave interactions cause the gravity wave spectrum to depart increasingly from a collection of independent, discrete, linear gravity waves as altitude and gravity wave amplitudes increase.

Of more direct relevance in terms of gravity wave effects in the middle atmosphere are the instabilities that lead to turbulence, gravity wave dissipation, and energy and momentum flux divergence. Important insights into the character of these instabilities can be obtained by employing various theories that describe possible instability character in

general sheared flows for which there is not a set of linear, orthogonal eigenvectors. Optimal perturbation theory (or singular vector analysis) enables the identification of both transient and 'global' perturbation characters and growth rates in general flows. Floquet theory similarly allows a perturbation analysis of spatially and temporally variable flows that typically corresponds to the global optimal perturbations that most often dictate finite-amplitude responses. Analytical and numerical efforts have also assessed instabilities accompanying wave-mean flow interactions, while direct numerical simulations (DNSs) offer an ability to evaluate instability dynamics and the resulting turbulence structure and morphology for idealized and more complex flows. These studies reveal multiple instabilities that depend to varying degrees on the characteristics of the underlying gravity waves and their environments. Here, we review those instability types that appear to contribute most significantly to gravity wave dissipation for various wave frequencies.

At near-inertial frequencies, gravity wave character is strongly influenced by rotation (see eqns [10] and [14]), they evolve slowly due to small vertical group velocities, and they support instabilities expected in approximately plane parallel shear flows. These include the familiar Kelvin-Helmholtz (KH) shear instabilities at Richardson numbers, $Ri = N^2(d\bar{u}_h/dz)^2 < 1/4$, and to an instability comprising counter-rotating rolls aligned along the shear when $N^2 < 0$. The latter instability closely resembles Langmuir circulations in a sheared ocean mixed layer, roll vortices in a sheared, convective atmospheric boundary layer, and the secondary instabilities that account for the transition to turbulence that arise in the highly sheared outer portions of KH billows at small Ri and sufficiently high Reynolds number, Re . A KH billow and secondary instabilities are illustrated in Figure 4 during the transition to turbulence for a shear flow having uniform N , $\bar{u}_h(z) = U_0 \tanh(z/h)$, where U_0 and h are the initial half velocity difference and the half shear depth, an initial $Ri = 0.05$, and $Re = U_0 h/\nu = 10\,000$.

Intermediate-frequency gravity waves exhibit wave 'breaking,' which can occur for waves that are convectively unstable or stable ($Ri \sim 1$ or greater), and Kelvin-Helmholtz instability (KHI), especially in the presence of mean wind shear or superposed gravity waves. Wave breaking can display a range of behaviors and orientations, depending on the gravity wave amplitude, intrinsic frequency, and Re . An example of wave breaking in a high-resolution DNS resolving the turbulence dynamics for a gravity wave having $a = 0.9$, $\omega_i = N/3.2$, a minimum flow $Ri \approx 3.8$, and $Re = \lambda_z^2/T_b\nu = 10\,000$, where $T_b = 2\pi/N$, is illustrated in Figure 5 with three-dimensional (3-D) images of λ_2 (a measure of flow rotation defined in terms of the rotation and strain tensors) during initial instability and following the transition to turbulence. Despite the high initial Ri , this gravity wave is highly unstable and exhibits a rapid transition to strong turbulence. Similar dynamics occur for a wide range of frequencies and spatial scales throughout the lower and middle atmosphere and can extend into the lower thermosphere for sufficiently large scales, amplitudes, and Re .

High-frequency gravity waves likewise exhibit a range of instabilities. Wave breaking at large amplitudes is similar to that for intermediate-frequency gravity waves. These gravity waves also enable instabilities accompanying evolution of the mean

Figure 4 KH billow structure depicted with vorticity magnitude for $Ri = 0.05$ and $Re = 10\,000$ at maximum billow amplitude. A streamwise-vertical cross section (left) shows vorticity maxima accompanying secondary instability structures having spanwise (smaller-scale KHI at the edges) and streamwise (billow interior) alignments. Streamwise-aligned instabilities in a spanwise-vertical plane at the top of the primary KH billow at the same time, and $\sim 0.1 T_b$ later, are shown at right. Figure 5 3-D vorticity structures during wave breaking for a gravity wave having $a = 0.9$, $\omega_i = N/3.2$, a minimum initial $Ri \approx 4$, and $Re = 10\,000$ separated by ~ 1.5 wave periods. Left views of the computational domain tilted along the gravity wave phase are from the side. Right views are from below. Strong vorticity is shown with yellow and red. The strongest turbulence accompanies plunging motions within the vortex rings seen forming at upper right. Fritts, D.C., Wang, L., Werne, J., Lund, T., Wan, K., 2009. Gravity wave instability dynamics at high Reynolds numbers, 2: turbulence evolution, structure, and anisotropy. *Journal of Atmospheric Sciences* 66, 1149–1171. doi:10.1175/2008JAS2727.1.

flow, termed ‘self-acceleration’ instability. This happens when the mean flow in which the wave resides is accelerated beyond the horizontal group velocity and is a consequence of the induced mean motion increasing as $\Delta \bar{u} \sim 1/\bar{\rho}$ because of its dependence on gravity wave momentum flux, $\bar{\rho} u_h' w'(z)$, whereas gravity wave velocities vary as $u_h' \sim 1/\bar{\rho}^{1/2}$. A DNS of such a self-acceleration event is shown in **Figure 6** with w' fields for a gravity wave packet localized in z , spanning 5 gravity wave periods, and having $\lambda_h = 20$ km and $\omega_i = N/1.4$. Instability accompanies the phase structure becoming vertical (fifth panel), which results from accelerations along the gravity wave propagation direction where amplitudes increase with time and decelerations where amplitudes decrease with time. Self-acceleration instability is 2-D, though 3-D instabilities also occur thereafter. The gravity wave amplitude decays and momentum transport ceases accompanying instability, resulting in local forcing that acts as a source of secondary gravity wave generation.

The instability dynamics reviewed above almost always occur in environments representing a superposition of gravity waves having a range of frequencies, spatial scales, and orientations. Such environments can significantly enhance the potential for instability and turbulence through interactions among finite-amplitude motions that readily yield flow deformations and energy transfers among modes (e.g., the $\mathbf{u} \cdot \nabla \mathbf{u}$ term in the Navier–Stokes equations contributing the advective terms in eqns [1]–[3]). Numerical studies of such complex dynamics are now becoming possible with nested mesoscale, high-resolution DNS, and large-eddy simulation models. Such simulations promise to significantly advance our understanding of these various dynamics throughout the atmosphere. An example of the turbulence dynamics arising from a simple superposition of a single gravity wave (with $a = 0.5$ and $\omega_i = N/10$) and fine-structure mean shears is shown for illustration in the top panel of **Figure 7**. This streamwise-vertical cross section

Figure 6 Streamwise-vertical cross sections of vertical velocity exhibiting gravity wave propagation and self-acceleration spanning ~ 5 wave periods. Maximum velocities increase from $\sim 2.5 \text{ m s}^{-1}$ initially to $\sim 60 \text{ m s}^{-1}$ in frame 5 and decrease as self-acceleration instability arises and the gravity wave dissipates. (Eds.), *Aeronomy of the Earth's Atmosphere and Ionosphere*. Springer, pp. 109–130.

Figure 7 Gravity wave instabilities (top panel) arising due to a superposition of a gravity wave having $a = 0.5$ and $\omega_i = N/10$ and fine-structure (FS) mean shears having a larger vertical wave number ($m_{\text{FS}} \sim 5 m_{\text{GW}}$) and maximum initial shear $d\bar{u}_h/dz = 2N$. KHI and wave breaking are seen occurring simultaneously at different altitudes due to the evolving gravity wave-FS superposition. Vertical profiles of potential temperature from $t = 0 - 24 T_b$ at $2 T_b$ intervals at the center of the computational domain. The image at the top is at $t = 11.5 T_b$ just before the seventh profile.

of the energy dissipation rate, ε , reveals a highly layered response and simultaneous wave breaking and KHI at different altitudes. The lower panel shows vertical profiles of potential temperature at two T_b intervals throughout the DNS that reveal the creation of ‘sheet and layer’ fine structure that closely resembles these structures often seen in high-resolution measurements in the atmosphere and oceans. These results suggest that multiscale interactions may play prominent roles extending from the atmospheric boundary layer into the thermosphere.

Middle Atmosphere Effects

Without wave forcing of the mean circulation of the middle atmosphere, the mean motion at middle and high altitudes would be in geostrophic balance, mean winds would increase continuously with altitude, there would be no wave-driven residual circulation, i.e., $(\bar{v}^*, \bar{w}^*) = 0$, the thermal structure would be in radiative equilibrium, and the winter polar mesopause would be cold and the summer polar mesopause would be warm. In reality, however,

gravity wave dissipation and momentum flux divergence in the mesosphere lead to body forces that decelerate the zonal mean winds, reverse the vertical shears in the mesosphere, and induce a wave-driven residual circulation with rising motions in the summer hemisphere, subsidence in the winter hemisphere, and strong meridional flow from the summer to the winter hemisphere near the mesopause. Rising and descending motions lead to adiabatic cooling and heating of the summer and winter mesosphere, causing a reversal of the meridional gradient of temperature imposed by solar radiation at lower altitudes and the coldest temperatures in Earth's atmosphere at the polar summer mesopause. A similar, but weaker, residual circulation occurs at lower altitudes, to which planetary waves

also make a significant contribution. Gravity wave contributions are due largely to mountain waves in winter, with both mountain and nonstationary waves contributing in summer. The impact of wave forcing, denoted (D_{F_x}, D_{F_y}) in eqns [25] and [26], effects on the mean wind and temperature profiles, and the character of the residual circulation at lower and higher altitudes, are depicted schematically in Figure 8. (For further discussion of the quasi-biennial oscillation (QBO) and semiannual oscillation (SAO), see **General Circulation of the Atmosphere: Overview.**)

At equatorial latitudes, geostrophic motions do not occur, and gravity wave filtering, dissipation, and momentum flux divergence contribute instead to forcing of two equatorial oscillations of the zonal mean wind at different altitudes. For

Figure 8 Schematic of winter and summer zonal wind profiles (top panel) and the wave-driven residual circulation (bottom panel). Solid (dashed) lines at the top show the observed (radiative equilibrium) profiles and red arrows indicate the mean body force accompanying gravity wave momentum deposition. Red (blue) regions at the bottom show eastward (westward) zonal jets, black arrows indicate the wave-driven circulation, and signs indicate heating and cooling due to induced vertical motions.

both the QBO and the SAO, gravity waves contribute to the forcing of each phase of the oscillation due to filtering and momentum deposition much as described above. In each case, gravity wave filtering in the lower phase of the oscillation imposes anisotropy on the wave spectrum that contributes to forcing of the opposite phase of the oscillation at greater altitudes. (For further discussion of the QBO and SAO, *see* **Middle Atmosphere**: Quasi-Biennial Oscillation; Semiannual Oscillation.)

Turbulence arising from gravity wave dissipation contributes both heating and transport through direct energy dissipation and mixing of local gradients of heat, momentum, and constituents. Turbulent mixing drives the thermal structure toward an adiabatic lapse rate ($\partial\bar{T}/\partial z = -g/C_p$), thus contributing to the mean thermal structure of the mesosphere. Because of the nature of gravity wave dissipation, however, mixing of heat and constituents is believed to be much less efficient than mixing of momentum. Turbulent mixing processes likely also play roles in gravity wave interactions with, and modulation of, larger scale tidal and planetary wave motions, given their significant responses to variations in local winds and static stability, such as so-called mesospheric inversion layers to which these large-scale dynamics frequently contribute. Relatively little is known about these dynamics at present.

Introduction

During the past four decades, a wide variety of remote and *in situ* observational techniques have revealed a rich spectrum of wave activity in the upper atmosphere, with horizontal wavelengths ranging from a few kilometers (km) to global scales and temporal periodicities ranging from a few minutes to about 2 weeks. In terms of decreasing spatial-temporal scales, the observed spectrum of freely propagating atmospheric waves is subdivided into planetary, inertia-gravity, and buoyancy (or acoustic-gravity) waves. Although physically similar to inertia-gravity waves, the buoyancy waves are of sufficiently small temporal and spatial scales that the rotation and curvature of the Earth play minor roles in determining their properties. Optical observations of these mesoscale (~ 10 – 1000 km horizontal wavelengths) waves are the primary focus of this article.

A complete spatial-temporal description of the global distribution of buoyancy wave sources has yet to be made, but a growing body of evidence indicates copious sources in the lower atmosphere. This is not particularly surprising since any perturbation of a stably stratified, low-dissipation region with frequency components between the high (Brunt-Väisälä) and low (Coriolis) frequency limits will generate buoyancy waves. The propagation of such waves in a realistic atmosphere will be strongly impacted by the background winds and temperature structure, producing such effects as refraction, reflection (complete or partial), and ducting (partial or complete). Hence, propagation of tropospherically generated buoyancy waves to the mesosphere and lower thermosphere (MLT) region (altitude range ~ 80 – 100 km) is not ensured, but the mesoscale waves observed in this region frequently exhibit downward phase progression, which is indicative of upward transport of energy from lower-atmospheric sources. In the upper mesosphere and lower thermosphere, processes involving viscosity and thermal conduction attenuate and dissipate energy for waves in the saturation region of growth. In [Figure 1](#), a simplified sketch captures much of the basic physics embodied in the modern concept of a realistic atmosphere permeated by packets of buoyancy waves.

It is now widely accepted that buoyancy waves with periods less than ~ 1 h achieve major importance in the MLT region because of the relatively large quantities of momentum (and to a lesser extent energy) that they transport to this region. In this connection, growth of many of the tropospherically generated buoyancy waves between their sources and the mesopause region is expected to increase their energy (per unit mass) by a factor of ~ 100 . A number of comprehensive experimental and theoretical evaluations of gravity-wave forcing have resulted in the conclusion that this process has a profound impact on the large-scale circulation in the MLT, as well as on the thermal and minor-constituent structures of the region. In addition, such forcing is expected to impact variability in the

MLT on many spatial and temporal scales as a result of various types of interactions such as wave-tide and wave-mean flow.

Optical Observations

Optical observations of buoyancy waves in the terrestrial upper atmosphere have been greatly facilitated by ‘nature’s gifts’ of several vertically distinct airglow layers, alkali metal layers, and noctilucent clouds (NLC). Some of the earliest evidence for atmospheric buoyancy waves was provided by wavelike deformations frequently observed during NLC displays. These are very tenuous mesospheric ice clouds (altitude ~ 82 km) that form during the summer months at high latitudes (typically $>55^\circ$) when the mesopause cools to the lowest temperature on Earth (110 – 150 K). As the clouds are tenuous, they can only be seen from the ground by the scattering of sunlight during the hours of twilight, when the observer and the atmosphere below the cloud layer are in darkness while the clouds themselves remain illuminated. (This condition occurs for solar depression angles between $\sim 6^\circ$ and 16° .) Optimum locations for observing mesospheric clouds now and over the past 100 years are Scandinavia/northern Europe, central Asia, and Canada in the Northern Hemisphere and the southern tip of South America in the Southern Hemisphere, where they are readily seen during the prolonged hours of twilight. An excellent example illustrating the wave forms frequently observed

Figure 1 Surrealistic representation of several key physical processes associated with the propagation of internal atmospheric gravity waves. Hines, C.O., et al., *The Upper Atmosphere in Motion*, Geophysical Monograph 18, American Geophysical Union, Part 2, Atmospheric Gravity Waves, 194, Figure 1.

Figure 2 High-latitude summer twilight photograph of noctilucent clouds at ~ 82 km altitude showing band-type buoyancy waves and many smaller-scale billows. Copyright of P. Parviainen, Finland, e-mail: pekka.parviainen@ppl.inet.fi.

in NLC is shown in **Figure 2**. The photograph clearly shows three large-scale NLC 'bands' with many smaller-scale, near-perpendicular, 'billow' waves. The average horizontal wavelengths associated with such deformations lie in the range 5–10 km (billows) and ~ 20 –50 km (bands), the latter of which are typical of the lower buoyancy range. It is interesting to note that current theories for the formation of NLC draw heavily on gravity-wave forcing from below to provide the requisite extremely cold near-mesopause environment during the summer months for successful ice nucleation and growth.

It is convenient to distinguish between *active* and *passive* optical methods for studying buoyancy waves. The active methods are usually associated with Rayleigh and resonant-scatter lidars that probe the vertical structure of temperature and/or density fields by studying the return signal from short, very intense, gated pulses of monochromatic light scattered by the upper-atmospheric medium. In contrast, most passive methods (with the exception of NLC) utilize the wave-induced spatial-temporal modulation of the airglow emissions to detect and study certain characteristics of the waves. The passive optical methods include various types of narrowband imaging, photometry/radiometry, and spectrometry/interferometry. Clearly, the lidar techniques yield direct information on vertical structure and motion, including the sense of vertical phase progression. In contrast, many of the passive techniques yield direct information on horizontal structure and motion and limited direct information on vertical structure when two or more layer observations are employed.

Lidar Measurements

With the development of powerful lidar systems in the 1980s, a new era of active remote sensing of the middle and upper atmosphere was born. Studies of buoyancy wave dynamics using lidars have emphasized Rayleigh scatter methods for investigating structure and wave motions in the stratosphere and lower mesosphere (~ 25 –70 km) and resonant scatter (e.g. using sodium) for studying waves in the MLT region (~ 80 –105 km). The low-altitude limit (~ 25 km) for the

Collins R.L., et al., 1996. Gravity wave activity in the upper mesosphere over Urbana, Illinois: lidar observations and analysis of gravity wave propagation models. *Journal of Atmospheric Terrestrial-Solar Physics* 58, 1905–1926, Figure 2.

stratospheric measurements is determined principally by signal distortion associated with Mie scattering from aerosols and particulates, whereas the upper-altitude limit (~ 70 km) results from limitations imposed by signal photon noise. In practice, each limit is determined by the characteristics of the particular lidar system (primarily its power-aperture product) and by the information retrieval methods used in the data analysis.

Lidar studies of wave dynamics in the mesopause region have utilized the alkali metal layers (e.g., Na and K) that are created primarily by the ablation of meteors in this region of the atmosphere. As Na is much more abundant and has a large back-scatter cross-section, it is the most well suited for buoyancy wave studies. In all cases, the lower- and upper-altitude limits of the measurements are determined by signal photon noise and/or information retrieval uncertainties. It is usually assumed that the Na atoms act as a passive tracer of wave dynamics under typical measurement conditions. However, extensive modeling studies of the chemistry of the Na layer and its response to wave forcing suggest that this basic assumption may be invalid for altitudes < 85 km. In addition, this assumption can be compromised under the special conditions that apply when sporadic layers form within the Na layer. This said, lidar studies represent one of the most powerful and advanced tools for sounding the atmosphere.

Current lidar studies of buoyancy waves provide a direct measure of vertical structure in Na number density induced by well-developed quasi-monochromatic events. Vertical wavelengths in the measurement range, typically 1 to ~ 20 km (limited by layer thickness), in the mesopause region and ~ 3 –30 km in the stratopause region are common. Quasi-monochromatic waves with observed periods in the range of several minutes (close to the local Brunt-Väisälä value) to several hours (usually limited by the data-record length) have been measured. However, in practice lidars have proven to be most sensitive to a class of waves with short vertical wavelengths (< 10 km) which exhibit relatively long observed periods and hence slow vertical phase progression. These waves tend to follow the so-called diffuse-damping limit for wave growth. **Figure 3** shows a sequence of Na layer profiles (~ 3 min spacing), tracing the downward progression of a well-developed long-period (5.8 h) buoyancy wave observed in the Na layer. This typical observation yielded a mean vertical

Table 1 Layer characteristics (full-width at half-maximum), except the Na layer which is of full width

Emission/layer	Peak altitude (km)	Width (km)
OI (557.7 nm)	96	6–10
O ₂ (0,1)	94	8–10
Na (589.2 nm)	90	~10
NIR OH	87	8–10
Na layer	92	80–105
NLC	82	2

wavelength of 6.9 km and a vertical phase velocity of -0.33 m s^{-1} , where the minus sign signifies downward phase progression, as illustrated in the figure. An inferred horizontal wavelength of about 450 km follows from these directly measured parameters. More sophisticated wind/temperature lidar systems have recently been developed that are capable of measuring temperature perturbations induced by long-period waves and tides (which are forced rather than freely propagating waves) and studying the background wind field through which the waves progress using thermal broadening and Doppler shifting of the resonance line. Together with the wave measurements these data can be used to estimate the sensible heat flux and vertical flux of horizontal momentum transported into the MLT region.

Image Measurements

Over the past 25 years the capability of imaging instrumentation for remote sensing faint structures in the upper-atmospheric nightglow emissions has evolved considerably. Early photographic observations demonstrating the existence of wavelike motions (akin to those seen in NLC) have been superseded by low-light, intensified TV cameras and more recently by solid state CCD imaging systems that now provide an exceptional capacity for quantitative studies of mesospheric wave motions.

Images of the naturally occurring nightglow emissions afford an excellent method for investigating the horizontal morphology and dynamics of short-period (typically $<1 \text{ h}$) buoyancy waves. To date, most imaging studies have utilized the bright near infrared (NIR) hydroxyl (OH) Meinel band emissions that originate from a well-defined layer (typical half-width $\sim 8 \text{ km}$) centered at $\sim 87 \text{ km}$. However, there are a growing number of observations of the NIR O₂ (0,1) atmospheric band emission at $\sim 865 \text{ nm}$ and the visible wavelength OI (557.7 nm) and Na (589.2 nm) line emissions. Although these emissions are considerably weaker than the broadband OH emission, they each exhibit well-defined nighttime profiles at different, but closely spaced altitudes in the MLT region. **Table 1** lists the properties of the nightglow emission layers together with the metal layers that are most frequently used in resonant lidar studies and the NLC layer characteristics. As the waves propagate and dissipate within the MLT region they induce significant modulations in the line-of-sight brightness (and rotational temperature) of these emission layers which is detected as 'structure'. Measurements of two (or more) nightglow emissions therefore provide an important additional

method for investigating the vertical as well as horizontal propagation of short-period buoyancy waves.

In particular, all-sky image data (180° field of view) yield unique information on the occurrence frequency, two-dimensional horizontal spatial characteristics, and the prevailing directionality of small-scale waves over an exceptionally large geographic area ($\sim 400 \text{ km}$ radius) corresponding to $\sim 500\,000 \text{ km}^2$ at MLT heights with high temporal and spatial resolution. These cameras are most sensitive to relatively fast-moving waves exhibiting vertical wavelengths somewhat greater than the layer thickness (i.e., $> 8 \text{ km}$) and horizontal wavelengths (λ_h) $\sim 5\text{--}200 \text{ km}$ (i.e., significantly less than the maximum field of view). In general, lidar and image measurements therefore sample different (but overlapping) regions of the buoyancy wave spectrum.

Optical measurements of the airglow emissions can be made at any latitude and season providing a global, all year round capability. Such studies, once limited to the realm of NLC, have revealed a wealth of small-scale wave activity at equatorial, mid- and high-latitudes from many sites around the world, and it is not uncommon to observe several different wave patterns during the course of a night suggesting copious sources. **Figure 4** illustrates a variety of wave patterns that are most commonly observed in the MLT emissions. These observations have mainly been made from mid- and low-latitude mountain sites, and distinct spatial and temporal properties have emerged which suggest the existence of two dominant types of short-period waves, termed 'bands' and 'ripples' (akin to those seen in NLC). **Figure 4(a)** illustrates the most prominent quasi-monochromatic pattern which usually appears as an extensive, coherent series of waves that exhibit horizontal wavelengths of a few to several tens of kilometers and horizontal phase speeds up to 100 m s^{-1} . Band displays are persistent, usually lasting for a few to several hours, and are spatially extensive, often occupying an area of sky much larger than the instantaneous all-sky field of view. In this image the bands appear as a series of curved waves (like the segments of an orange) due to the format of the all-sky lens. However, when they are mapped into geographic coordinates they often (but certainly not always) appear as an extensive series of quasi-planar waves. In this example the wave pattern appeared linear and exhibited a horizontal wavelength of $38 \pm 2 \text{ km}$, and an observed phase speed of $34 \pm 3 \text{ m s}^{-1}$ indicating an observed period of $19 \pm 2 \text{ min}$. The histogram plots of **Figure 5** illustrate the range of values typically observed for bands.

In contrast, the second type of wave motion (termed ripples) is quite distinct from the bands, exhibiting much smaller spatial and temporal scales. Ripples usually occur in localized wave packets that occupy much smaller regions of the sky, typically $< 5 \times 10^3 \text{ km}^2$. They have relatively short lifetimes (a few minutes to $\sim 45 \text{ min}$) and almost always exhibit periods close to the local Brunt-Väisälä period ($\sim 5 \text{ min}$). Two ripple patterns are also evident in **Figure 4(a)** superimposed on the band-type wave pattern. The similarity between the wave forms seen in this image and the narrow angle NLC of **Figure 2** is striking.

The importance of multilayer measurements is illustrated in **Figure 4(b)**, which shows wave structure imaged in the Na emission layer at approximately the same time as **4(a)**. (Note that the bright lines are due to an Na lidar beam probing two

Figure 4 Example all-sky (180°) images illustrating the dominant spatial signatures of short-period buoyancy waves observed frequently in the MLT nightglow emissions. Adapted from Taylor, M.J., et al., 1995. All-sky measurements of short-period waves imaged in the OI(557.7 nm), Na(589.2 nm) and the near infrared OH and O₂(0,1) nightglow emissions during the ALOHA-93 campaign. *Geophysical Research Letters* 22, 2833–2836, Figure 1.

regions of sky during the 120 s image exposure.) The same band pattern is clearly evident in this emission (and in the OH and O₂ emissions) indicating that this wave motion was coherent and extended vertically throughout the MLT region whereas the ripples are absent revealing their limited horizontal and vertical extent.

A likely source of ripples and billows is the chance combination of wind and long-period wave motions (including tides) creating localized regions of strong wind shear which then generate small-scale waves *in situ* through the Kelvin–Helmholtz instability. Alternatively, the waves may be generated by a three-dimensional convective-type instability which

predicts that the waves should form near-orthogonal to the perturbing wave. In each case, the wave patterns will be short lived and spatially localized as evident from the image data. In contrast, the band-type waves have been shown to be due to freely propagating or ducted buoyancy waves most probably of tropospheric origin.

Figure 4(c), (d) depicts different class of band-type motion termed a ‘frontal event’. Unlike most band patterns this type of wave is characterized by a sharp leading edge followed by a discrete number of (typically <10) trailing wave crests, similar in morphology to a bore on a river. This type of wave motion is much less common and is thought to be the

Figure 5 Histogram plots illustrating the typical ranges of horizontal wavelength, phase speed and observed period associated with short-period gravity wave patterns. Figure 6 Map illustrating a relatively complex wave display imaged in the OI(557.7 nm) and O₂(0,1) nightglow emissions and consisting of two quasi-linear wave patterns and one curved wave train. Taylor, M.J., et al., 1995. All-sky measurements of short-period waves imaged in the OI(557.7 nm), Na(589.2 nm) and the near infrared OH and O₂(0,1) nightglow emissions during the ALOHA-93 campaign. *Geophysical Research Letters* 22, 2833–2836, Figure 2.

signature of a trapped (or ducted) wave propagating near-horizontally at mesospheric heights. In this case, the effect of the bore intrusion on the airglow layers was to simultaneously lower the height of the NIR OH (image d) and raise the OI (557.7 nm) layer (image c) which is manifested as a reversal in contrast to the structuring.

Figure 4(e) shows another example of band-type wave structure ($\lambda_h = 35.5 \pm 1.0$ km) but this time imaged in the high-latitude ($\sim 65^\circ$ N) OH emission from central Alaska. The bright arc in the lower part of the image is due to auroral precipitation. Joule heating and other forcing associated with solar-induced magnetic storms are a known source of large-scale buoyancy waves that are often detected in the high-altitude ionosphere as traveling ionospheric disturbances (TIDs). However, in this case the bands were moving towards the auroral zone suggesting other, tropospheric-type sources.

These examples have been chosen for their clarity to illustrate the types of short-period wave motions that exist at MLT heights. However, as one would expect from the quasi-random ensemble of sources and waves propagating into the upper atmosphere (as depicted in the sketch of Figure 1) there are oftentimes many more waves evident, resulting in a complex, time-varying airglow pattern. Such a situation is shown in the OI (557.7 nm) image of Figure 4(f). In this case two bandtype motions progressing in almost orthogonal directions are evident. A map illustrating the geographical location and orientations of an even more complex wave display observed over the Hawaiian Islands is shown in Figure 6. The display consists of two quasilinear wave patterns and one curved wave train. The temporal evolution of these events reveals the true/exceptionally dynamic nature of the MLT region.

Figure 7(a), (b) shows two narrow angle images depicting exciting new evidence of wave breakdown creating turbulent structures. The two images show a portion of a well-developed

band pattern ($\lambda_h = 27$ km) which appears to increase in contrast, as the wave becomes nonlinear (image a) and then breaks into a number of much smaller scale turbulent features (image b). Such observations are currently rare, yet it is expected that the breakdown of these waves to smaller scale sizes eventually resulting in turbulence and the associated transfer of energy and momentum into the background medium is a major driver of the MLT region dynamics.

Ground-based, airborne, and, most recently, satellite-borne image measurements have been employed to study buoyancy waves. The advantage of satellite-based measurements is their ability to study waves and their potential sources over remote, inaccessible areas on a global scale. This new capability is illustrated in Figure 8, which shows data from the Midcourse Space Experiment (MSX) providing the first observations from space of gravity waves generated by a thunderstorm over Indonesia. In this case, the data are nadir pointing from the midwave infrared CO₂ emission at 4.3 μ m in the upper stratosphere (altitude 40 km) and show circular wave fronts ($\lambda_h = 25$ km) launched by a ‘pointlike’ thunderstorm at their center. Until recently most satellite measurements have focused on much larger horizontal scale size ($\lambda_h \sim$ a few thousand kilometers), longer period waves that can be readily discerned in limb airglow measurements. However, this new nadir capability is poised to revolutionize our understanding of wave generation and propagation in the middle atmosphere on a global scale.

Interferometry, Photometry, and Spectrometry Measurements

Interferometers, photometers (radiometers), and spectrometers continue to play major roles in quantifying the line-of-sight-integrated intensity and temperature responses of the airglow

Figure 9 Ground-based measurements of OH Meinel (3,1) band emission illustrating the intensity and rotational temperature signatures induced by the passage of a short-period (~ 6 -mm) buoyancy wave. Courtesy Utah State University.

layers to buoyancy waves. For quasi-monochromatic events, the ‘layer-averaged’ amplitude of the perturbing wave can, in principle, be obtained directly from the observed temperature variation. However, in practice, an accurate determination of the wave amplitude requires a knowledge of the background temperature structure, the distribution of emitters in the layer, and the vertical wavelength of the wave. This information set is seldom, if ever, available. Furthermore, the column emission rate (CER) response is less directly related to the amplitude of the induced perturbation. As a result, ratio of the fractional perturbations in CER and temperature (which is independent of wave amplitude) has become the key parameter in comparing experiment with theory.

In their simplest operating mode (static, single field), these instruments continue to provide much useful information for testing the predictions of sophisticated chemical–dynamical models for the layer response. For example, [Figure 9](#) shows the response of the OH Meinel airglow layer to short-period ($\cong 5.8$ min) buoyancy waves near the Brunt–Väisälä limit as measured by a high-throughput Michelson interferometer. A train of six oscillations clearly illustrates that the high-frequency wave-induced fractional temperature perturbations are nearly an order of magnitude smaller than the fractional CER perturbations. As the induced perturbation amplitudes

for such highfrequency waves are expected to be small (typically $\leq 1\%$), precise measurements pose a significant experimental challenge.

In their more sophisticated multifield or imaging modes, these instruments have provided useful information on the horizontal spatial scales and motions of the waves, in addition to defining the integrated layer responses to perturbations induced by the waves. Furthermore, as with imaging studies, measurements using two (or more) vertically distinct airglow emissions (e.g., OH and O₂ (0,1) bands) provides a means for assessing horizontal and vertical scales of motion and the amplitude of wave growth.

Introduction

Under the influence of gravity, a fluid of variable density settles into a configuration in which surfaces of constant density are approximately horizontal and density decreases with height. Such a fluid is said to be stably stratified. Stratification is an important property of geophysical flows, affecting motions over a wide range of spatial and temporal scales. The buoyancy of a fluid parcel (or of a solid object) suspended within a fluid describes the tendency of the parcel or object to move upward or downward in response to gravitational and pressure-gradient forces. Buoyancy might be regarded as an effective ‘force’, but it actually represents a combination of these two fundamental forces. Coherent oscillations resulting from the restoring force of buoyancy are known as buoyancy waves, or gravity waves; these waves play an important role in atmospheric dynamics.

Buoyancy

The vertical acceleration of a parcel of fluid is governed by

$$\frac{dw}{dt} + g + \frac{1}{\rho} \frac{\partial p}{\partial z} + \cdots = 0 \quad [1]$$

where w is the vertical component of velocity, d/dt denotes the material derivative following the parcel, g is the acceleration of gravity, ρ is density and p is pressure. Linearizing the second and third terms of eqn [1] about a basic state in hydrostatic balance, such that

$$p = \bar{p} + p' \quad [2a]$$

$$\rho = \bar{\rho} + \rho' \quad [2b]$$

and

$$\frac{\partial \bar{p}}{\partial z} = -\bar{\rho}g \quad [3]$$

the equation may be written

$$\frac{dw}{dt} + g \frac{\rho'}{\bar{\rho}} + \frac{1}{\bar{\rho}} \frac{\partial p'}{\partial z} + \cdots = 0 \quad [4]$$

The second term describes the buoyancy of a parcel:

$$b' \equiv -g \frac{\rho'}{\bar{\rho}} \quad [5]$$

implying a tendency for lighter parcels to accelerate upward, and vice versa, under the influence of gravity. The buoyancy variable in eqn [4] acts as an effective ‘force’ in the vertical direction.

In a nondiffusive incompressible fluid, density is conserved following the motion:

$$\frac{d\rho}{dt} = 0 \quad [6]$$

which may be linearized about a state of rest and combined with the definition of buoyancy variable to give

$$\frac{\partial b'}{\partial t} + w'N^2 = 0 \quad [7]$$

where

$$N^2 \equiv -\frac{g}{\bar{\rho}} \frac{\partial \bar{\rho}}{\partial z} \quad [8]$$

is the Brunt–Väisälä frequency squared, a quantitative measure of stratification. N^2 is positive in a stably stratified fluid. In this case, N is the frequency of oscillation of a fluid parcel about its equilibrium level of neutral buoyancy, as can be seen, for example, by combining eqn [7] with the fully linearized version of eqn [4] and neglecting the vertical pressure gradient force.

In an ideal gas, potential temperature θ is conserved following the motion (apart from diabatic effects) and may be used as a surrogate for density in the definition of buoyancy. This approximation is valid if the speed of sound is large and the effect of the pressure perturbation on density is thereby minimized. The corresponding definition of N^2 is

$$N^2 \equiv \frac{g}{\bar{\theta}} \frac{\partial \bar{\theta}}{\partial z} \quad [9]$$

so that potential temperature increases with height in a stably stratified atmosphere. In this case, once again, N is the frequency of oscillation of an air parcel about its equilibrium level of neutral buoyancy.

Unlike solid objects that are shape-preserving, fluid parcels are stretched and deformed by the motion; buoyant plumes entrain or detrain fluid while mixing with the environment. The concept of buoyancy, as applied to individual parcels, is therefore of limited use except in special situations where the integrity of parcels is maintained. Moreover, individual parcels are rarely able to move about without affecting neighboring ones. Buoyancy remains important, nonetheless, because it influences the collective motion of parcels coupled together by the fundamental forces. Stratification affects virtually all classes of atmospheric motion. It is particularly important for buoyancy waves – more commonly known as gravity waves – which arise in a stably stratified flow as a result of the restoring force of buoyancy.

Buoyancy Waves

Gravity waves exist in two forms: internal and external. The most common type of external wave propagates horizontally along the interface between two fluids of different density, with amplitude diminishing away from the interface. Internal waves, on the other hand, propagate horizontally and vertically in a fluid of continuously varying density or potential

temperature. Internal waves are more important in the atmosphere. While propagating vertically, gravity waves transport horizontal momentum vertically, often over many density scale heights. To conserve wave energy, the amplitude of a gravity wave generally grows with altitude because of the density decrease, so that a small perturbation (perhaps undetectable in the lower atmosphere) becomes large in the middle and upper atmosphere. Momentum is irreversibly deposited in a region where the waves attain large amplitude and become locally unstable (e.g., at a critical level (see later)), breaking via convective or shear instability. Vertical mixing of heat and constituents also can be attributed to gravity-wave breaking.

Gravity waves assume the form of plane waves, consisting of alternating slabs of fluid sliding upward or downward at an angle, as illustrated in Figure 1. They also appear with surfaces of constant phase radiating diagonally from a two-dimensional source (e.g., a vibrating horizontal rod) or as conical phase surfaces in three dimensions emanating from a point source. Waves originating from a point source appear as concentric rings in a horizontal cross-section, and have been observed in the stratosphere above isolated thunderstorms.

Figure 1 depicts a plane wave with phase propagation downward and to the right. For this wave the group propagation is upward and to the right, orthogonal to the direction of phase propagation as is generally the case with gravity waves. A downward propagating phase is commonly observed in the middle atmosphere, suggesting upward group propagation and a tropospheric source. An upward propagating phase is sometimes observed in the troposphere, suggesting downward group propagation and an upper tropospheric source. In other cases, upward group propagation is observed throughout the

Figure 1 Structure of an internal gravity wave with phase propagation downward and to the right. Contours indicate zonal velocity, vertical velocity, or pressure, with negative values shaded. Rising and sinking motions produce adiabatic cooling and warming, respectively. The resulting temperature anomalies are in quadrature with the pressure anomalies, leading the pressure anomalies by a quarter-cycle.

troposphere, indicating a source near the surface. Vertical transport of horizontal momentum is in the direction of vertical group propagation, as implied by the positive correlation of horizontal and vertical velocity components in Figure 1.

In a simple mean flow without shear, or slowly varying in time and space, the intrinsic frequency of a vertically propagating gravity wave must lie in the range

$$|f| < |\hat{\omega}| < N \quad [10]$$

where f is the local Coriolis frequency. The intrinsic frequency is

$$\hat{\omega} = \omega - \mathbf{k} \cdot \bar{\mathbf{u}} \quad [11]$$

where ω is the wave frequency relative to the coordinate system, $\mathbf{k}$ is the wavevector, and $\bar{\mathbf{u}}$ is the mean flow, assumed horizontal. The special situation $\hat{\omega} = 0$ (relevant if $f = 0$) is illustrated in Figure 2, and is referred to as the Hines critical circle, named after its inventor Colin Hines, an atmospheric scientist of the latter half of the 20th century who has written extensively on the role of gravity waves in the middle atmosphere. This circle traces out a locus of points for which the component of mean flow velocity in the direction of horizontal wave propagation equals the horizontal phase speed of the wave, $c = \omega/k$, where k is the horizontal wavenumber. Equivalently, for any phase velocity vector extending from the origin to a point on the circle, the mean flow speed $|\bar{\mathbf{u}}|$ matches the apparent speed of wave crests in the direction of the mean flow.

When the wavevector and mean-flow vector are parallel, the wave is said to have a critical level at the altitude where mean-flow speed and horizontal phase speed are equal. Waves with

Figure 2 Hines's critical circle for plane waves with horizontal component of wavevector, $\mathbf{k}^*$, normalized to unit length in a mean flow $\bar{\mathbf{u}}$, assumed horizontal. Along the circle, the mean flow speed projected onto the direction of wave propagation is equal to the wave's horizontal phase speed, c .

Figure 3 Potential temperature surfaces displaced by an upward propagating internal gravity-wave packet experiencing exponential growth with height in a compressible atmosphere. The wave is about to overturn and break in the upper part of the domain, beginning at the breaking level, z_b .

upward group propagation, approaching a critical level from below, grow to large amplitude, overturn, and break in a critical layer of finite depth lying below the critical level. In a compressible atmosphere where density decreases with height, waves generally grow in amplitude with height, with or without shear, and eventually break. This situation is illustrated in [Figure 3](#), showing potential temperature surfaces distorted to such an extent that some of these surfaces are about to overturn and create conditions for local static instability. Parcels within a convectively unstable region experience exponential growth of displacement amplitude with time, quickly restoring a locally stable configuration. The process of wave breaking leads to turbulence generation, momentum deposition, mixing, and diminution of wave amplitude, and in some cases, excitation of waves not present in the original spectrum.

Waves with intrinsic frequency near f are known as inertia-gravity waves. The effect of positive f is illustrated in [Figure 4](#). A vertical profile of horizontal velocity would look something like the hodograph in [Figure 5](#), with phase increasing downward ($m < 0$). Horizontal wind components obtained from a balloon ascending rapidly through this wave would exhibit clockwise rotation with height, indicating upward group propagation. Velocity data displayed in this format are informative. The eccentricity of the ellipse (a/b) indicates the ratio

Figure 4 Structure of an inertia-gravity wave in the Northern Hemisphere, where the Coriolis parameter f is positive. Features resemble those of the internal gravity wave shown in [Figure 1](#), but with a meridional component of velocity included. Eastward and westward zonal wind anomalies generate southward and northward meridional wind anomalies, respectively, in quadrature with the zonal wind anomalies, and positively correlated with the temperature anomalies.

Figure 5 Hodograph of horizontal wind components for the inertia-gravity wave of [Figure 4](#). The horizontal component of the wavevector points in the positive x -direction, along the major axis of the ellipse. The vertical wavenumber m is negative, so that phase decreases with height.

of wave intrinsic frequency to local Coriolis frequency, while the orientation of the major axis indicates the direction of horizontal phase propagation, to within 180° . This directional ambiguity can be resolved if simultaneous temperature data are available, as implied by [Figure 4](#). In addition to a vertical flux of momentum, the inertia-gravity wave contributes to a horizontal flux of heat transverse to the direction of horizontal phase propagation.

Inertia-gravity wave parameters are related through a dispersion relation

$$(\hat{\omega}^2 - f^2)m^2 = (N^2 - \hat{\omega}^2)k^2 \quad [12]$$

where k and m are horizontal and vertical wavenumbers, respectively. This formula is valid for waves on an f -plane, in a constant or slowly varying mean flow, under the incompressible approximation; it is also approximately valid for atmospheric waves with vertical wavelength $\lambda_z \ll 4\pi H$ where $H = -(1/\rho) \times (d\rho/dz)$ is the density scale height where ρ is the horizontally averaged density. Most waves of interest satisfy this inequality. It can be seen from the dispersion relation that when the intrinsic frequency approaches f , the vertical wavenumber increases to infinity, i.e., the vertical wavelength approaches zero. The presence of f^2 in eqn [12] implies a larger vertical wavenumber than would otherwise be the case without the Coriolis force. One implication of this result is that inertia-gravity waves may break down via shear instability rather than via convective instability as wave amplitude increases.

According to eqn [12], waves with large intrinsic frequency have relatively steep surfaces of constant phase, while waves with small intrinsic frequency have relatively flat surfaces of constant phase. That phase surfaces become vertical in the limit $\hat{\omega} \rightarrow N$ is intuitively reasonable since N is the frequency of oscillation for vertical displacements in a stably stratified fluid. In this limit, the vertical group velocity and vertical wavenumber go to zero, and the waves are reflected from the surface where $\hat{\omega} = N$. In the opposite limit $\hat{\omega} \rightarrow f$, the vertical group velocity also approaches zero, but the vertical wavenumber approaches infinity, and the waves are likely to break and be absorbed.

Gravity waves are sometimes trapped in vertical waveguides or 'ducts' and are able to traverse a large horizontal distance. Long-period waves have relatively small vertical group velocity and are also able to propagate over a range of latitudes, so that the value of f seen by the waves changes slowly with time. Near the equator, inertia-gravity waves may become trapped within an equatorial waveguide, forming a modal structure, or equatorially trapped inertia-gravity wave. These modes constitute the 'fast manifold' of waves on an equatorial beta plane. The intrinsic period of equatorial inertia-gravity waves can be longer than a day, in contrast to mid-latitude gravity waves which are typically restricted to a range of intrinsic periods from several minutes to several hours.

There are several sources of gravity waves in the atmosphere, including flow over topography, convection, shear instability, and geostrophic adjustment. Orographic excitation is favored when surface winds are strong and directed across undulations of the topography. Convection generates gravity waves through pulsations in forcing or through a 'topographic' effect as the convective plume impinges on a stably stratified shear layer. Organized clusters of convection also generate gravity waves, but on a much larger scale than that of individual clouds. Sometimes the clusters themselves are organized by inertia-gravity waves to form a coupled moist dynamical system. This behavior is observed in the tropics,

over open ocean. Shear instability generates larger-scale gravity waves through envelope radiation. Geostrophic adjustment has long been regarded as a source of gravity waves radiating away from a state of initial imbalance. A similar process, the spontaneous emission of gravity waves, is now recognized for its role in evolving large-scale flows, such as baroclinic instabilities, in which regions of imbalance are generated through formation of frontal zones and regions of strong ageostrophic acceleration.

Gravity waves have several important effects on the general circulation of the atmosphere. They can accelerate the flow spontaneously, giving rise to such phenomena as the quasibiennial and semiannual oscillations of the tropical middle atmosphere. Gravity waves also decelerate the flow, reducing the speed of the winter polar night jet, summer mesospheric jet, and the topside of the tropospheric jet stream. These waves stimulate weather events in the troposphere, such as precipitation bands and new convective elements. Convection therefore is not only a source of gravity waves, but is also triggered by gravity waves generated by distant convection.

Simulation of the atmospheric general circulation requires either a proper parametrization of gravity-wave effects, or explicit simulation of the waves. Because gravity waves span a wide range of horizontal scales, it is impractical to simulate the entire spectrum. In most models, some combination of explicit modeling and parametrization is utilized.

Gravity Waves Excited by Jets and Fronts

Synopsis

Jets and fronts are known to be significant sources of gravity waves. This has been shown by numerous studies with real-data observations and/or numerical models. Case studies have highlighted the jet exit region as particularly favorable to low-frequency gravity waves. They have also identified wave ducting as a key maintenance mechanism for waves propagating over long distances near the ground. A number of observational studies also hypothesized that the primary mechanism for wave generation in the jet exit region is geostrophic adjustment, which has been recently generalized to the concept of spontaneous balance adjustment. However, the precise mechanisms responsible for the generation of these waves remain an active area of research. Further research remains necessary to draw a more complete picture of waves in the vicinity of jets and fronts, assessing the relevance of theoretical results on one hand, and the importance of other factors that contribute to the gravity waves, in particular moist processes and topography.

Introduction

In midlatitudes, jet/front systems have been known to be sources of gravity waves for a long time. More precisely, jets and fronts are associated with motions on fairly small scales (a few to a few hundred kilometers) and part of these have clearly been identified as gravity waves. Several essential elements leading to the generation of gravity waves from jets and fronts have been understood, yet the complexity of the flow is such that no simple diagnostic is readily available for a quantitative prediction of waves generated near jets and fronts. In such a complex, three-dimensional and time-dependent environment, the propagation of the waves needs to be considered alongside with their generation. The combination leads to the characteristics and amplitude of the waves that are found.

Such mesoscale waves are important for tropospheric dynamics and convection in the vicinity of fronts, for small-scale motions (mixing and turbulence) in the tropopause layer near upper-level jets, and for the energy and momentum transport that affects the general circulation of the atmosphere. The description of the latter, in climate models, depends in part on parameterizations of gravity waves. The description of nonorographic sources at midlatitudes remains unsatisfactory to date, and calls for a better understanding and knowledge of waves emanating from jets and fronts.

Below, we first review evidence from observations showing that jets and fronts are significant sources of gravity waves. Next, the elements of understanding coming from theoretical studies are presented. Open issues and current challenges are then discussed.

Observational Evidence

Gravity waves in the vicinity of jets and fronts have been identified in observations for several decades, both in case studies and in more statistical investigations. The focus has expanded, over the years, from tropospheric waves, typically detected in networks of surface barographs, to upper-tropospheric and stratospheric waves, detectable from a variety of different

measurements (radar, radiosondes, superpressure balloons, and satellites).

Early case studies have identified a configuration of the flow regularly present in events of intense gravity waves in the troposphere. In a midlatitude baroclinic wave, it consists of the region downstream of an upper-level jet, cold-air side of the surface front and close to the ridge of geopotential (Uccellini and Koch, 1987, see Figure 1, adapted from Koch and O'Handley, 1997). The relevance of this paradigm has been confirmed numerous times in subsequent case studies. For example, in the lower troposphere, Bosart et al. (1998) have documented an intense gravity wave observed in a midlatitude cyclone on the eastern coast of the United States (Figure 2). As the wave propagated northward along the coast, ducting in the lower layers and amplification of the wave played major roles, with the pressure falls reaching 13 hPa over a period of 30 min. Such large-amplitude waves in

the lower layers can have impacts on the organization and enhancement of moist convection but are challenging to be accurately simulated in convection-permitting models (Zhang et al., 2001). At upper levels, such waves emanating from jets have a potential to create regions of clear-air turbulence by modulating a background shear. In regions where the gravity wave enhances the shear, the latter can become sufficiently strong to become unstable (Lane et al., 2004).

Several other studies also identified the exit region of the upper-level jet as the source for stratospheric gravity waves (Guest et al., 2000; Hertzog et al., 2001; Wu and Zhang, 2004)

using sounding or satellite measurements in combination with numerical models and/or ray-tracing techniques. Other regions of the flow have also been highlighted as significant from observational case studies. First, jet exit regions upstream of a trough also appear favorable for enhanced gravity wave activity (Plougonven et al., 2003). In several studies of waves from upper-level jets, gravity waves have been found above and below the jet, propagating upward and downward, respectively. This is clear evidence that, in these cases, the jet is the source. These waves typically have intrinsic frequencies close to the Coriolis parameter (often called inertia-gravity waves). In

contrast to this, the vicinity of a cold front has also been highlighted as a source, in particular when significant wind impinges on the front (e.g., [Ralph et al., 1999](#)).

Complementary to case studies, observational evidence showing gravity waves from jet/front systems also comes from statistical studies, i.e., studies that examine small-scale motions in a large number of observations and relate those to likely sources (e.g., [Fritts and Nastrom, 1992](#); [Koppel et al., 2000](#); [Guest et al., 2000](#)). Many different types of observations can be used to identify gravity waves, from *in situ* measurements by high-resolution radiosondes, to global remote-sensing observations from satellites. Each type of observation will see only a part of the gravity wave spectrum. For example, high-resolution profiles of horizontal wind from radiosondes or Doppler radars are well suited to identify low-frequency gravity waves which have a clear signature in the hodograph (curve obtained from plotting u as abscissa and v as vertical coordinate), and waves with vertical wavelengths rather smaller than 10 km. Satellite observations from limb sounders, on the other hand, will capture deep gravity waves ([Alexander et al., 2010](#)). Presently, there is an ongoing effort to combine the knowledge acquired from the different datasets available, complemented by outcome of numerical models, in order to obtain a global estimation of the gravity wave field.

Global descriptions of the gravity wave field obtained from satellite observations typically highlight several large-scale regions with enhanced gravity wave activities: regions of orography, the Tropics, and the winter midlatitudes associated, respectively, with mountain waves, convective waves, and waves from jets and fronts. Often, maps will tend to highlight the hotspot regions of orography on the pass of large scale jet streams where the largest wave amplitudes are often found. Yet the area covered by storm tracks where waves from jets and fronts are found can be larger (e.g., [Wu and Zhang, 2004](#)). A quantitative comparison of the momentum fluxes integrated over a latitude band due to either source has been carried out using measurements from long-duration superpressure balloons flying in the lower stratosphere. Recent campaigns around Antarctica in austral spring have showed that, integrated over latitude circles, the contribution to momentum fluxes from gravity waves over the oceans was at least comparable to that from orographic waves ([Hertzog et al., 2008](#)).

In summary, observations have provided compelling evidence regarding the importance of jets and fronts as sources of gravity waves, and have identified several configurations particularly favorable to gravity waves, in particular jet exit regions. Mechanisms of generation, however, have not been clearly identified from observations alone. Starting in the 1990s, case studies have frequently included numerical simulations with a mesoscale meteorological model as complementary to observations (e.g., [Powers and Reed, 1993](#); [Zhang et al., 2001](#)). The more complete description of the flow that is provided by simulations allows a further investigation of generation mechanisms. Numerical simulations have highlighted the complexity of the flow, which is three-dimensional and time-evolving. Indeed, for a given wave event, there are generally several processes occurring, each of which may influence the emission and maintenance of waves (emission from the jet and/or front, interaction with topography and/or moist processes leading to amplification of the waves, ducting,

etc.). In consequence, there can be several interpretations to a given gravity wave event, even with the full description of the event available from a full three-dimensional numerical simulation. Different mechanisms have been described theoretically that contribute to generating and modulating the waves. This is currently a very active area of research, as it is difficult to isolate and describe quantitatively these source and maintenance mechanisms, for fundamental reasons as outlined below. A more extensive review of this subject can be found in [Plougonven and Zhang \(2014\)](#).

Theoretical Understanding

One would wish for a simple idealized model of gravity wave emission from jets and fronts that would capture the essential physics, as the linear study of constant flow over orography conveys the essential physics to start understanding orographic waves. Unfortunately, in contrast to orographic waves, it is not an external element which introduces short (intrinsic) timescales in the flow and hence forces gravity waves. It is the internal dynamics which produces these short timescales, making the problem much more difficult. Theory has nonetheless described several mechanisms that explain the propagation or the generation of some of the waves present in the vicinity of jets and fronts. Below we successively describe wave ducting, then paths that have been followed to illustrate how balanced motions can lead to the emission of gravity waves, and finally summarize recent studies which quantitatively explain low-frequency gravity waves that are found near jet exit regions.

Some elements of understanding have been obtained for quite a long time regarding the behavior of gravity waves near jets and fronts. Namely, in many early studies of waves detected near the surface, propagating away from a surface front, it was shown that the environment was such as to guide and maintain waves near the surface. These are called ducted waves ([Eom, 1975](#)). Ducting occurs when a stable layer is present near the ground, capped by a layer which efficiently reflects waves (e.g., of low stability, possibly beneath a critical level) ([Lindzen and Tung, 1976](#)). The presence of such a duct has been highlighted in many case studies (e.g., [Powers and Reed, 1993](#); [Zhang et al., 2001](#)). This emphasizes an important point: the background environment in which the waves propagate is very important, and it can help select some of the characteristics of the waves present.

The mechanisms for generation of the waves, on the other hand, have long remained elusive; quite often geostrophic adjustment has been referred to as the generation mechanism. Indeed, as a baroclinic wave grows in amplitude, one can diagnose a region of increasing imbalance (using diagnostics such as Lagrangian Rossby numbers or the residual of the nonlinear balance equation). Part of this imbalance takes the form of mesoscale gravity waves. Case studies have repeatedly shown the relevance of identifying regions of imbalance, which can be identified even in a coarse-grained description of the flow ([Koch and Dorian, 1988](#); [Bosart et al., 1998](#); [Zhang et al., 2001](#)).

Classical geostrophic adjustment theories typically describe the evolution of either small perturbations to a fluid at rest, or

of perturbations to a flow that has a symmetry (zonally symmetric flow or axisymmetric flow) (Rossby, 1938; Blumen, 1972). In both cases, balanced motions and gravity waves decouple, so that the geostrophic adjustment problem is well-posed and analytical treatment becomes possible. Geostrophic adjustment constitutes a fundamental building block of our understanding of motions in a stratified, rotating fluid. It illustrates how, in a first approximation, motions decompose into slowly evolving motions near geostrophic balance and fast gravity waves. However, to understand how gravity waves are excited by jets and fronts, one needs to understand more precisely in what circumstances these motions couple, and how some imbalance energy may continuously be produced from the balanced motions and to generate gravity waves. One also needs to consider higher-order balance than geostrophy. To generalize the classical geostrophic adjustment theory, Zhang (2004) introduced the concept of (spontaneous) balance adjustment under which the large-scale synoptic background flow such as baroclinic jet-front system continuously produces flow imbalance (away from nonlinear balance that is more precise than geostrophy) which continuously forces gravity waves. A framework to describe spontaneous balance adjustment has been proposed (Plougonven and Zhang, 2007) and its successful use to describe waves emitted in dipoles will be described further below, at the end of the present section.

An important nondimensional number which indicates the relevance of balanced dynamics is the Rossby number. Consider a flow with L a typical length scale and U a typical velocity. The Rossby number is the ratio of the inertial timescale, $1/f$, where f is the Coriolis parameter, and the advective timescale, L/U :

$$Ro = U/fL \quad [1]$$

When $Ro \ll 1$, this indicates that advection occurs on timescales much longer than the fastest of the gravity waves (inertia-gravity waves with periods close to the inertial period). The dynamics is then well captured by approximations which describe the part of the flow that is tied to the advection of potential vorticity, i.e., the balanced or vortical part of the flow. Now, jets and fronts are predominantly balanced motions: they are rather well described by assuming the flow to be near geostrophic and hydrostatic balance. Such assumptions lead to approximations, such as quasigeostrophy, which simplify the flow by explicitly filtering gravity wave motions. Higher-order approximation, such as *semigeostrophy*, has been shown to describe essential features of frontogenesis. In other terms, the theoretical models available to understand fronts exclude gravity waves by construction.

Therefore, determining what gravity waves are generated from jets and fronts requires to understand how the evolution of flows that are balanced initially leads to emission of gravity waves. This *spontaneous emission* (or spontaneous adjustment emission, SAE) is quite distinct from classical geostrophic adjustment problems, in which the imbalance is prescribed in the initial conditions. Quantifying spontaneous emission sheds light on the limitations of balanced models, but this is an arduous problem which has motivated numerous studies over the past three decades.

Three pathways for spontaneous emission have been identified and quantified analytically and are briefly discussed here: Lighthill radiation, unbalanced instabilities and transient

generation in shear. Lighthill radiation is the emission of large scale waves by small-scale balanced motions which have frequencies high enough to project onto the gravity wave spectrum (Ford et al., 2000), i.e., for which $Ro > 1$. The study of this mechanism builds on the pioneering work of James Lighthill (1924–98) who had described the generation of acoustic waves from turbulent motions. Although this mechanism applies to waves generated from intense vortices in the atmosphere, the scale separation described does not transpose to waves emanating from jets and fronts. The other two mechanisms, unbalanced instabilities and transient generation in shear, couple balanced motions and gravity waves in flow configurations with $Ro \ll 1$. An unbalanced instability involves both balanced and unbalanced motions, and is therefore absent from all balanced models, whatever their accuracy. Unbalanced instabilities have been calculated for a wide range of flows, and have recently been observed in the laboratory, but they generally have weak growth rates (see Plougonven and Zhang, 2014 and refs. therein). Transient generation in shear is the emission of waves from sheared anomalies of potential vorticity. This emphasizes that in a nontrivial background flow, the decomposition into balanced motions and gravity waves is no longer well-defined, in contrast to small perturbations in a fluid at rest. For both mechanisms, the main point to retain is that shear allows to couple ‘slow’ and ‘fast’ motions because of Doppler shifting. The waves have been quantified analytically and are exponentially small in Ro , i.e., their amplitude typically scales as

$$\exp(-\alpha/Ro) \quad [2]$$

with a prefactor that may include an algebraic dependence in Ro , and where α is a constant. In practice, such a dependence implies that the waves seem absent for small Ro , and appear to ‘turn on’ past a finite value of Ro . Such results have been obtained using sophisticated asymptotic techniques (see Vanneste, 2013 and refs. therein) and constitute valuable milestones. However, the mechanisms described above do not relate straightforwardly to cases of inertia-gravity waves in the vicinity of jets and fronts. Flow configurations closer to those observed have been obtained by investigating flows of intermediate complexity using idealized numerical simulations.

Much understanding of baroclinic waves and frontogenesis has come from idealized simulations of these processes. Likewise, idealized simulations of frontogenesis and of baroclinic life cycles have provided essential elements of understanding for gravity waves generated from jets and fronts (Snyder et al., 1993). The first simulations of baroclinic life cycles with a hemispheric model (O’Sullivan and Dunkerton, 1995) confirm the presence of inertia-gravity waves emitted from the upper-level jet in simulations initiated from an initially balanced jet. However, the model grid resolution they used raised concern of possible numerical artifacts.

With increasing computing power and the development of mesoscale meteorological models, it became possible to run an idealized simulation with nested domains allowing a resolution fine enough to be confident that the waves were well resolved (Figure 3). The waves found in these simulations differed from the previous ones, had shorter scales and larger amplitudes. Both upper-level jets and surface fronts were shown to contribute, in different ways. Gravity waves from

Figure 3 The 13-km pressure (thick blue line, every 2 hPa), horizontal divergence (thin red line; solid, positive; dashed, negative; every $5 \times 10^{-6} \text{ s}^{-1}$), and wind vectors (maximum of 25 ms^{-1}) simulated from the triple-nested mesoscale model MM5 with horizontal (vertical) resolutions of 10 km (360 m). The wind speed at 8 km (near the maximum jet strength level) greater than 45 ms^{-1} is shaded in gray (every 5 ms^{-1}). The distance between tick marks is 300 km. Adapted from Figure 12d of Zhang, F., 2004. Generation of mesoscale gravity waves in upper-tropospheric jet-front systems. *Journal of Atmospheric Science* 61(4), 440–457.

these high-resolution multiply nested mesoscale model simulations as shown in Figure 3 (Zhang, 2004) are to a large extent consistent with the conceptual model of Uccellini and Koch (1987; Figure 1) that are derived from observational mesoscale gravity wave case studies.

In many cases, both from observations and from idealized case studies, jet exit regions have been emphasized as a favored locus for the presence of intense inertia-gravity waves. This suggested that this region was particularly relevant for generation. It turned out to be insightful to consider also the propagation of the waves. Indeed, jet exit regions are characterized by strong strain and important vertical shears. Simple considerations (a WKB approach) on the propagation of a wave packet

in a background flow made of a pure deformation field and vertical shear was shown to lead to waves with a specific intrinsic frequency and with phase lines oriented along the extensional axis of the deformation field. This is consistent with the orientation and intrinsic frequencies of waves simulated and observed in such regions. This phenomenon has been called ‘wave-capture’, and has been emphasized as providing a route for the background flow to lead a gravity wave to dissipation (as the wavelength contracts) (Bühler and McIntyre, 2005). Whereas the implications for wave-mean flow interactions remain an area of investigation, the relevance of these ‘propagation effects’ have been verified and illustrated in a number of idealized studies (Plougonven and Snyder, 2005, 2007; Lin and Zhang, 2008; Wang et al., 2010).

Albeit idealized, baroclinic life cycles remain complex (three-dimensional, time-evolving flow). More detailed and quantitative understanding of the wave generation process has been obtained over recent years by focusing on a yet simpler flow: vortex dipoles in a continuously stratified fluid. This constitutes a simple model of jet streaks. It is truly three-dimensional, retains a local maximum of wind speed, and hence a region of deceleration where streamlines are diffluent. Yet it greatly simplifies the flow relative to baroclinic life cycles, because it propagates nearly steadily. More precisely: the simulated dipoles were not exact steadily propagating solutions to the model equations, but their evolution had timescales (tens of days) much longer than those of gravity waves, making it possible to consider that a dipole is stationary in the appropriate comoving frame.

Numerical experiments have been carried out by several groups with very different numerical models and configurations (Snyder et al., 2007; Viudez, 2008; Wang et al., 2009). A robust phenomenology emerged from these simulations, with a wave packet found in the front of the dipole, in the jet exit region, with phaselines, intrinsic frequencies and sensitivity to resolution that are consistent with expectations from wave-capture (Figure 4). In initial times of the different simulations, an adjustment takes place, but the vertical velocity then settles down to a pattern that is essentially stationary in the frame moving with the dipole. For small Rossby number ($Ro < 0.05$),

Figure 4 Idealized simulation of a surface dipole, with a conspicuous wave packet emitted in the jet exit region. The left panel shows vertical velocity at altitude $z = 62.5 \text{ m}$ (colors), and potential temperature (contours). The right panel shows a vertical cross section along the axis of the dipole, with vertical velocity (colors) and horizontal velocity in the plane of the cross section (contours). All axis labels are in kilometers. Adapted from Figure 9 of Snyder, C., Muraki, D.J., Plougonven, R. and Zhang, F. 2007. Inertia-gravity waves generated within a dipole vortex. *Journal of Atmospheric Science* 64, 4417–4431. © American Meteorological Society. Used with permission.

no easily detectable wave signal is found, whereas for the finite Rossby numbers that can be attained ($0.1 < Ro < 0.2$) the waves may dominate the vertical velocity field (Snyder et al., 2009; Wang et al., 2009).

The generation of the waves in these dipole experiments is explained by decomposing the flow into a balanced approximation of the dipole and a correction (Snyder et al., 2009; Wang and Zhang, 2010). The correction can be considered a solution of equations that are linearized about the balanced dipole. Now the latter is not an exact solution, so that when injected into the full equations it yields nonzero residual tendencies. These provide a forcing for the correction. In the center of the dipole, advection is strong, leading to short intrinsic timescales. In this region the waves are generated, and their propagation in the jet exit influences the characteristics consistent with wave capture (McIntyre, 2009). It is essential in the above that the equations for the corrections are linearized about the dipole flow. This background flow is three-dimensional and strongly constrains the waves that emerge. Intuitions built on models of wave emission in a fluid at rest are not applicable here.

The above discussion has not touched on another pathway for energy to be transferred from balanced motions to gravity waves: shear instability is expected to occur in regions where frontogenesis leads to very intense shears. It has been suspected for nearly four decades that this could constitute a source of gravity waves (e.g., Jones, 1968; Mastrantonio et al., 1976). However, it has been difficult to quantify this emission. Linear stability analysis shows that, in general, the most unstable modes due to shear will be of Kelvin–Helmholtz type, occurring on scales too short (intrinsic frequencies too high) to connect directly to gravity waves. Part of the energy of the unstable motions may project onto gravity waves, through fluctuations of the envelope of the unstable region, or by the geostrophic or balanced adjustment in this region once it has been partially and rapidly mixed by the instability. It is necessary to describe a wide range of scales to quantify this emission, from the large scale of the baroclinic disturbances (a thousand kilometers) to the short scales (a few kilometers) of the instability. This hinders the precise estimation of waves from this source, which remains an open issue.

Open Questions and Challenges

One remarkable outcome from observations and numerical modeling has been the robustness of the paradigm put forward by Uccellini and Koch (1987), and the dynamical understanding obtained since. The convergence of different approaches (observational case studies, idealized simulations) and the recurrence of this configuration in numerous studies are indications of the robustness of this result. Theory has highlighted propagation effects, either through wave-ducting of Lindzen and Tung (1976) or in ‘wave-capture’ of Bühler and McIntyre (2005), as mechanisms for maintaining and enhancing IGW in certain regions of the flow, the large-scale environment determining certain of the wave characteristics. The emission mechanism has been explained as the linear response to the differences between the balanced and the full tendencies. The key point is that the dynamics are linearized on the background of an approximation of the dipole.

This constitutes an encouraging, positive result, but several issues remain to be explored: it is necessary to go back to real flows with this enhanced theoretical understanding, to confirm that the characteristics of the waves are indeed consistent with those expected from propagation effects in the shear and strain present. The amplitudes of waves in idealized experiments have repeatedly been found to be weaker than in observations, and this constitutes a second issue. More importantly, in both idealized simulations and real flows, other sources of waves need to be assessed, and in particular sources that lead to waves with shorter scales and higher intrinsic frequencies, which may carry significant contributions to momentum fluxes toward the stratosphere (Fritts and Alexander, 2003). Simulations and observations have provided indications that such waves are present, but their shorter scale makes them more difficult to identify and quantify, let alone to predict.

In coming years, a major challenge will be to bring together descriptions of gravity waves from different observation sets and from high-resolutions modeling (Alexander et al., 2010). Tying gravity waves quantitatively to diagnostics of the tropospheric flow will be an important goal. Several possible routes for such a relation have been suggested, but a systematic, quantitative assessment of their relevance remains to be undertaken. Furthermore, theoretical studies so far have concentrated on dry dynamics, yet case studies have often emphasized moist processes, at least as amplifying waves. Recent studies showed that moisture may lead to significantly enhanced gravity wave activities in the vicinity of jets and fronts (Waite and Snyder, 2012). In the idealized simulations of moist baroclinic waves, Wei and Zhang (2014) found that not only moist convection can be triggered by dry gravity waves from jet streaks, it can significantly enhance the parent gravity waves by as much as orders of magnitude, along with additions of high-amplitude and high-frequency smaller scale gravity waves. The interactions of jet-front systems with convection and/or topography in the generation of gravity waves remain to be thoroughly explored. Such progress in the quantitative understanding of waves near fronts will be an important step for understanding the impact of gravity waves to the general circulation, and for the improvement of parameterizations of gravity wave effects in climate models.

Convectively Generated Gravity Waves

Synopsis

Atmospheric convection is an important source of gravity waves. The gravity waves are caused by vertical displacements of stable air associated with convective elements, along with the diabatic heating and cooling within moist convection. Gravity waves can be generated by shallow or deep convection and the waves normally propagate vertically and horizontally away from their source. While in the troposphere, convective gravity waves can affect the stability and modify further convective development. In the troposphere, stratosphere, and mesosphere the dissipation of convective gravity waves exerts a tendency on the mean flow and thereby contributes to the momentum budget of those layers.

Underlying Theory and Generation Mechanisms

Dry thermals or plumes represent the simplest model of a convective cloud. Consider an isolated warm perturbation (i.e., a thermal) in a stratified environment. The thermal will have positive buoyancy and be accelerated upward. Once the thermal reaches the altitude where its temperature is equal to that of the environment, known as the equilibrium level, its buoyancy will be zero but it will continue to rise due to its existing upward momentum. As the thermal penetrates above the equilibrium level, the thermal will have negative buoyancy and be forced to return to the equilibrium level. Hence an oscillation of the thermal ensues, which also causes an oscillation of the stable air above and below the thermal's boundary. This oscillation generates gravity waves that radiate away from the thermal. See the model simulation in Figure 1.

Here, the thermal is analogous to a simple harmonic oscillator with the restoring force provided by buoyancy associated with the stable stratification. However, the oscillation is damped by entrainment processes that dilute the buoyancy and by the flux of momentum and energy away from the thermal caused by the propagating waves. Thermals in neutral environments do not generate gravity waves, except if they impinge upon a stable interface like an inversion at the top of the convective boundary layer.

The pattern of waves generated by the thermal shown in Figure 1 is similar to the classical St Andrew's cross pattern obtained in laboratory experiments. That pattern is obtained in the laboratory using a cylindrical solid body oscillating in a stratified fluid. Consider the two-dimensional linear equations of motion for an inviscid Boussinesq fluid, which are:

$$\frac{\partial u}{\partial t} + U \frac{\partial u}{\partial x} = -\frac{1}{\rho_0} \frac{\partial p}{\partial x}, \quad [1a]$$

$$\frac{\partial w}{\partial t} + U \frac{\partial w}{\partial x} = -\frac{1}{\rho_0} \frac{\partial p}{\partial z} + b, \quad [1b]$$

$$\frac{\partial b}{\partial t} + U \frac{\partial b}{\partial x} + w N^2 = 0, \quad [1c]$$

$$\frac{\partial u}{\partial x} + \frac{\partial w}{\partial z} = 0, \quad [1d]$$

where u is the horizontal velocity perturbation from the mean horizontal velocity U , w is the vertical velocity, p is the perturbation pressure, ρ_0 is the reference density, b is the buoyancy, N is the Brunt-Väisälä frequency, x and z are the horizontal and vertical coordinates, respectively, and t is time. Here $N^2 = (g/\theta_0)(d\theta/dz)$, where g is the gravitational acceleration, θ is the potential temperature, and θ_0 is its reference value; the buoyancy is defined as $b = g\theta'/\theta_0$, where θ' is the perturbation potential temperature. The St Andrew's cross wave response can be easily reproduced in numerical experiments with the solid body replaced by an isolated oscillating source of momentum or heat applied to the right hand sides of eqns [1a–b] or eqn [1c], respectively.

For example, Figure 2 shows results from two numerical experiments that apply a periodic source of localized heating and cooling to eqn [1c] (and solve eqns [1a–d]). This diabatic forcing has the form $Q = Q_0 q(x, z) \cos(\Omega t)$, where Ω is the source frequency and for this example q is a Gaussian function in the horizontal and a half sinusoid in the vertical (see Figure 2 for the outline of the forcing). In these experiments the background wind, U , is zero. The diabatic forcing is a simplified representation of a moist convective cloud; waves generated by real clouds will be reflected at the ground; and wave propagation characteristics will change with vertical variations in wind and stability. As with real clouds, gravity waves are generated that propagate in both horizontal directions away from the source.

When the amplitude of the oscillation is small (i.e., nonlinear effects can be neglected), the wave frequency, ω , is equal to the source frequency, Ω . The frequency of the source and the Brunt-Väisälä frequency of the environment determine the angle of the wave phase lines from the vertical, α . Specifically the dispersion relation for two-dimensional linear gravity waves in the absence of background flow is

$$\frac{\omega^2}{N^2} = \frac{k^2}{m^2 + k^2} = \cos^2(\alpha), \quad [2]$$

where k is the horizontal wave number, m is the vertical wave number, and the horizontal and vertical wavelengths are $\lambda_x = 2\pi/k$ and $\lambda_z = 2\pi/m$, respectively. Thus, for all else equal, a higher frequency source generates waves with phase lines that are oriented closer to the vertical than a lower frequency source. This property is illustrated in Figure 2. When $|\Omega| > N$ the

Figure 1 Numerical simulation of a thermal evolving in a stably stratified environment (with $N = 0.02 \text{ s}^{-1}$). The black-edged white line is the thermal boundary. Colored shading represents buoyancy with positive values pink and negative values green and blue. Vertical velocity is contoured black (at intervals of $\pm 0.025, \pm 0.05, \pm 1, \pm 2 \text{ m s}^{-1}$) with negative values dashed.

generated waves are evanescent, which means that their amplitude decays exponentially with height (and satisfy $m^2 < 0$).

Linear theory of gravity waves also shows that in steady background flows that only vary in the vertical (i.e., flow with no horizontal variations in mean wind speed or stability), the horizontal phase speed $c = \omega/k$, the horizontal wavelength, and the wave frequency are all conserved following a wave packet. In such a framework, gravity waves respond to vertical variations in stability and horizontal wind through changes in the vertical wave number. The influence of changes in horizontal wind on gravity wave properties can be incorporated into eqn [2] as

$$\frac{(\omega - Uk)^2}{N^2} = \frac{k^2}{m^2 + k^2} = \cos^2(\alpha), \quad [3]$$

where terms involving wind shear and wind curvature have been neglected for simplicity. The 'intrinsic frequency', $\omega - Uk$, is the wave frequency in a frame of reference moving with the

wind. Unlike the actual wave frequency (ω), the intrinsic frequency is not conserved and therefore changes in the wind will modify the vertical wavelength and the angle of the phase lines from the vertical. If, for example, U increased above a convective cloud or thermal, it can be shown that the phase lines of the waves propagating into the wind shear vector would be tilted toward the vertical and those propagating with the wind shear vector would be tilted to the horizontal. If this change of wind is sufficiently large, such that $|\omega - Uk| > N$, the waves propagating into the wind shear vector would become evanescent. Alternatively, a wave critical level would occur for those waves propagating with the wind shear vector if $\omega - Uk = 0$, and the waves would be dissipated in some way (e.g., wave breaking).

The examples provided in Figure 2 created gravity waves by applying an external source of diabatic heating and cooling. Diabatic forcing in moist convection is derived from phase changes of water: condensation causes heating and evaporation causes cooling. However, dry convection (i.e., thermals)

Figure 2 Vertical velocity patterns generated by localized thermal forcing in a stratified environment with $N = 0.01 \text{ s}^{-1}$. The forcing periods ($2\pi/\Omega$) are 1 h (left) and 2 h (right), and the solutions are shown at time (t) that satisfies $\cos(\Omega t) = 1$. Pink through white colors are upward motion and green through black colors are downward motion. The region of forcing is outlined with the black-edged white line.

generates gravity waves via adiabatic processes, which means that there is no diabatic forcing on the right-hand side of eqn [1c] associated with phase changes of water. Instead, the wave generation is associated with internal body forces caused by the oscillating thermals. These body forces can be represented mathematically as forcing on the right hand side of eqns [1a–c] that is sourced from nonlinear processes within and around the oscillating thermals.

Moist convective clouds generate gravity waves via a combination of diabatic forcing and nonlinear body forces. The heating and cooling associated with condensation and evaporation explains part of the wave spectrum. The typical life cycle of a mesoscale convective system (MCS) is characterized by mean heating and cooling that is transient with timescales greater than about an hour. Accordingly, the transient heating and cooling explains waves with periods greater than about an hour, with horizontal wavelengths defined, in part, by the horizontal extent of the system. The flow shown in Figure 2 is directly analogous to this generation process.

Convective updrafts embedded within MCSs behave similarly to thermals (e.g., Figure 1) and can be represented by nonlinear body forces within the clouds. Like thermals, convective updrafts overshoot their equilibrium level and generate waves with frequencies that are close to the Brunt–Väisälä frequency; thus, these waves can have periods as small as 10 min, i.e., shorter than the typical convective life cycle of about an hour or more. The horizontal wavelength of these waves is related to the width of the convective updrafts, which can be smaller than the overall size of the MCS that the updrafts are embedded within. Deep convective clouds that span the troposphere contain convective updrafts that

overshoot the tropopause, which can increase the amplitude and frequency of the generated waves considerably.

The generation of updrafts and downdrafts within moist convection is, however, ultimately related to diabatic processes and it could be argued that the diabatic processes are responsible for all of the wave generation. However, for deep clouds the overshoot and oscillation of convective updrafts occurs in the upper troposphere or lower stratosphere, where latent heating is weaker (due to the smaller mass of condensed water) and a large part of the wave generation occurs due to the vertical displacement of stable air above the cloud, where the flow is adiabatic (i.e., internal body forces). Although there is no definitive separation of scales, it is instructive to consider the wave generation as a combination of two separate processes: (1) diabatic forcing from phase changes of water that generates waves with spatial and temporal scales similar to the size and life cycle of convective systems and (2) internal nonlinear body forces associated with oscillating updrafts that generate waves with horizontal wavelengths closer to the size of individual convective updrafts and wave frequencies that approach the Brunt–Väisälä frequency.

Tropospheric Waves

Some of the earliest observations of convective gravity waves were made by glider pilots above boundary layer thermals. Glider pilots exploit the ascending motion within the waves to achieve enhanced lift, and their experiences provided motivation for a number of early studies. Like the examples discussed so far, the thermals penetrate and exert a body force on the inversion at the top of the mixed layer, and the response of the

vertically displaced stable air generates gravity waves. The horizontal wavelengths of the waves are directly related to the size of the thermals, and in conditions without wind shear the spectrum of waves is rich, contains a range of scales, and the spectrum of phase speeds is close to symmetric relative to the mean flow. However, it is common for there to be wind shear at the top of the mixed layer, which can create a coherent wave pattern in the troposphere that appears close to monochromatic.

Changes in wind speed and stability within and above the boundary layer can shape the spectrum due to vertical variations in wave propagation. As described earlier, variations in the wind and stability affect the vertical wavelength of gravity waves, which corresponds to changes in the wave's vertical group velocity. As waves propagate vertically, vertical variations in the environment can lead to wave evanescence ($|\omega - Uk| > N$), which more readily affects the highest-frequency waves and/or those with short horizontal wavelengths (i.e., large k). The waves can also encounter a wave critical level and be dissipated at altitudes where the background wind becomes equal to the phase speed of the waves ($c = \omega/k$). Critical level interactions first affect those waves with slow phase speeds relative to the mean flow that propagate in the same direction as the wind shear vector. The combined

effect of evanescence and critical level interactions is often termed 'wave filtering.'

An example of waves above a convective boundary layer is presented in Figure 3. This idealized case features a mixed layer about 1.5–2 km deep, a background wind that is zero in the mixed layer and equal to 5 m s^{-1} in the free troposphere, and a shear layer that extends between approximately 2 and 3 km altitude. This example illustrates how the shear layer filters the waves: between 2 and 3 km altitude, shorter wavelength waves are present with amplitudes that decay with height. Above the shear layer the wave field is coherent and being dominated by waves with horizontal wavelengths equal to approximately 5 km. The process of wave filtering also reflects some wave energy downward, and those reflected waves help determine the horizontal scale of the thermals in the mixed layer, i.e., the convection and the waves it generates interact with one another via a feedback process. This resonant process is thought to explain some occurrences of regularly spaced boundary layer clouds and shallow cloud bands.

Deep convection can also be influenced by the gravity waves in the troposphere, with populations of deep clouds and the waves they generate interacting via a complicated feedback process. The lower-frequency waves generated by diabatic forcing within the clouds probably make the most important

Figure 3 Numerical simulation of gravity waves generated by a (dry) convective boundary layer. Lines are contours of vertical velocity (at 0, ± 0.25 , ± 0.5 , ± 1 , ± 2 , ..., m s^{-1} intervals) and gray shading denotes upward motion. Adapted from Lane, T.P., Clark, T.L., 2002. Gravity waves generated by the dry convective boundary layer: two-dimensional scale selection and boundary layer feedback. *Quarterly Journal of the Royal Meteorological Society* 128, 1543–1570.

contribution to these wave–convection interactions. Precipitating deep convection normally generates a set of gravity waves with different vertical wavelengths that are related to the depth of the convective systems and the vertical distribution of latent heating and cooling. The longest vertical wavelength will be twice the depth of the convection and is related to the depth of the diabatic heating profile. The next longest wavelength is approximately equal to the depth of the convection and related to upper-level heating and low-level evaporative cooling in the system (i.e., the so-called ‘stratiform heating’ profile). When the convection extends to the tropopause, the vertical structure of these waves also corresponds to harmonics of the tropospheric depth (Z_T). These waves are commonly referred to as the $n = 1$ and $n = 2$ waves, with corresponding vertical wavelengths equal to $2Z_T$ and Z_T , respectively. Shorter vertical wavelength waves (and higher-order tropospheric harmonics) are also generated by the complexities in the vertical structure of the clouds and the range of cloud depths in cloud populations.

The $n = 1$ and $n = 2$ waves generated by deep convection have relatively long periods and therefore propagate at an angle close to the horizontal. Long-lived convection generates $n = 1$ and $n = 2$ waves with long periods and appears like horizontally propagating bores; shorter-lived convective systems generate $n = 1$ and $n = 2$ waves with periods of a few hours. The change in stability at the tropopause also acts to partially reflect the waves, and coupled with the relatively long wave periods, can cause $n = 1$ and $n = 2$ waves to extend significant horizontal distances from the convective systems while remaining in the troposphere. These waves also propagate quickly: in the hydrostatic limit ($k \ll m$) the horizontal phase speed relative to the mean flow is equal to N/m and for typical values of the stability and tropopause height the speed is approximately 30–50 and 15–25 m s^{-1} , for $n = 1$ and $n = 2$ waves, respectively. See Figure 4 for a schematic.

The deep tropospheric gravity waves generated by convection communicate the diabatic heating and cooling within the clouds to their environment. In doing so, these waves can either stabilize or destabilize their environment, which can suppress or promote further convection. The first phase of the $n = 1$ wave normally features descending motion that extends over

the entire tropospheric depth. The subsidence stabilizes the atmosphere and suppresses convection in the immediate vicinity. Following the onset of precipitation, the $n = 2$ wave is generated and its first phase is normally ascent in the lower half of the troposphere and descent in the upper half. This low-level ascent destabilizes the atmosphere, either creating a region of preferred convective development around the convective system or initiating new convection when convective inhibition is sufficiently low.

The property of the $n = 1$ and $n = 2$ waves in modifying the environment of convective systems has been used to explain aspects of cloud organization and the upscale growth of convective systems. Convective systems in the tropics are known to be ‘gregarious,’ and the destabilizing effects of gravity waves explain the rapid growth in area of convective activity around mesoscale convective complexes in the tropics. A theory known as wave-conditional instability of the second kind (CISK) attempts to explain the propagation of convective systems as a result of gravity wave-induced convergence. However, in many cases the application of this theory is challenged because the gravity wave speeds and system propagation speeds are different. Nonetheless, other studies have demonstrated that in the tropics gravity waves can organize the cloud population through creating a sequence of convective initiation events, or by modulating the cloud population and determining the spacing of convective elements.

Although many studies have focused on tropical regions, where the convective inhibition is normally low and wave effects are maximized, vertical variations in the background shear and stability in the midlatitudes can lead to ducting of waves, which amplifies their role in convective initiation. Studies have shown success in explaining the propagation of some midlatitude convective systems using a combination of wave ducting and wave-CISK (called ‘ducted wave-CISK’). Forward protruding storm anvils can also define a local wave duct ahead of convective systems; waves in that duct have been shown to cause discrete system propagation. In many ways, convective systems and the tropospheric waves they generate are intertwined and inseparable; and gravity waves are an important part of system morphology and longevity.

Figure 4 Schematic of the vertical structure and horizontal propagation of the $n = 1$ and $n = 2$ tropospheric waves from a precipitating convective system. Curves represent the vertical structure and sign of the temperature perturbations associated with each wave, and vertical arrows represent the corresponding vertical motion associated with the first phase of each wave. Horizontal arrows represent the horizontal phase speed, c , with the range of typical values also shown.

Stratospheric Waves

The stratosphere is normally about twice as stable as the troposphere (in terms of its Brunt–Väisälä frequency, N) and permits the vertical propagation of the high-frequency waves generated in the troposphere by convection. These highest-frequency waves have phase lines that are oriented closer to the vertical than lower-frequency waves and the vertical component of their group velocity can be similar in magnitude to the horizontal component. Consequently, these waves often occur in the stratospheric air directly above convective systems. Nonetheless, as the waves propagate horizontally as well, the total horizontal area affected by high-frequency gravity waves eventually exceeds the horizontal area of the convective system that generated them.

Figure 5 illustrates the pattern of waves in the stratosphere above a numerically simulated isolated midlatitude convective system. (The tropopause is at approximately 12 km altitude in this case). The wave fronts are approximately circular, with the center of the fronts corresponding to the convective system itself. As is typical, the horizontal wavelength of the highest-frequency waves is smaller than the width of the convective system and corresponds to the size of individual convective updrafts. Gravity waves with horizontal wavelengths as small as 5 km have been observed directly above active convection by aircraft, consistent with those shown here. Organized MCSs comprises multiple regions of active convection and often

Figure 5 Results from a model simulation of an isolated thunderstorm. The portion of the cloud that penetrates above 10 km altitude is shown by the lower surface. Isentropic surfaces at approximately 15 and 20 km altitudes are also shown.

show separate sets of circular wave fronts; each set of wave fronts is centered on a different region of active convection within the system. The result can be complex interference patterns in the wave field in the stratosphere, with additional complexity arising from source intermittency as convective regions become active and decay with time.

Convective clouds generate a spectrum of waves and lower-frequency waves that are not directly attributable to overshooting updrafts that also reach the stratosphere. For example, $n = 1$ and $n = 2$ waves are only partially reflected at the tropopause and propagate into the stratosphere as well. Typical wave periods above isolated convection can range from 10 min to a few hours, horizontal wavelengths range from ~ 5 to >50 km, and there is a corresponding range of horizontal phase speeds. For example, Figure 6 shows an example spectrum of the vertical flux of horizontal momentum (ρuw , where ρ is the density and u and w are the perturbation horizontal and vertical velocities, respectively) at 20 km altitude above a numerically simulated midlatitude squall line. For upward propagating waves the sign of the momentum flux is equal to the sign of the phase speed relative to the mean flow, and the fluxes in this figure are consistent with upward propagating waves in an environment moving at approximately 10 m s^{-1} . In this example, peaks in the spectrum exist at phase speeds between approximately 10 and 30 m s^{-1} in magnitude relative to the 10 m s^{-1} background flow.

Although the examples presented earlier in Figures 1 and 2 showed symmetric wave patterns, the waves shown in Figures 5 and 6 show that the waves and their spectrum are different for the different propagation directions. This asymmetry occurs for two main reasons: wave generation and wave propagation.

Long-lived convective systems, like squall lines, usually feature convective updrafts that are tilted in the vertical. Studies have shown that although tilted updrafts generate gravity waves propagating in all horizontal directions, the largest amplitude waves generated are normally those that propagate in the direction of the updraft tilt. The tilted structures project onto that part of the wave spectrum more efficiently than other parts, generating an asymmetric spectrum of gravity waves.

The spectrum of waves at a given altitude in the stratosphere is also shaped by changes in wind shear and stability between that altitude and the convective wave source, i.e., wave filtering. Filtering by wind shear can create significant asymmetries in the stratospheric wave spectrum, which is closer to symmetric in the absence of shear. Moreover, as illustrated by Figure 5, the shortest gravity waves are often filtered in the upper troposphere and lower stratosphere, leaving only the longer wavelength waves further aloft.

The motion of convective systems, viz. advection and propagation, complicates interpretation of the dynamics underlying the wave generation. Analyzing the wave spectrum in a frame of reference moving with the convective source (as opposed to the ground-based reference frame, e.g., Figure 6) is sometimes illustrative. However, choosing this reference frame is complicated by the fact that individual convective cells often propagate at a different velocity to the MCSs they are embedded within. Some studies have shown, however, that when the convective updrafts move with the mean wind at their equilibrium level, the peaks in the spectrum occur at similar phase speeds in all directions relative to that reference frame.

Figure 6 Spectrum of the vertical flux of horizontal momentum (in units of N m^{-2} per 1 m s^{-1} bin) vs horizontal phase speed above a numerically simulated squall line. Results from two simulations are shown that use horizontal grid spacing of 2 km (solid) and 125 m (dotted).

Sheared flows with an ensemble of cloud top heights can broaden the spectrum considerably because the ensemble of wave sources moves at different speeds.

Organized convective systems, viz. systems larger than a single convective cell that persist for multiple convective overturn times, generate gravity waves with horizontal wavelengths beyond the scale of individual clouds. As convective clouds become organized, the spectrum of gravity waves broadens to encompass longer wavelengths and longer periods that are related to the spatial scale of the organized system and its lifetime. For example, regions of organized convective activity in the tropics can contain a rich spectrum of multiscale convective systems and may include individual clouds, MCSs, mesoscale convective complexes, clusters, and superclusters. Each of these systems generates gravity waves leading to a spectrum that contains notable contributions from horizontal wavelengths of 10 km through to scales beyond 1000 km. Waves with these longer wavelengths can be influenced by the Earth's rotation and are then classified as 'inertia-gravity waves.' The intrinsic period of inertia-gravity waves can be tens of hours. (The minimum intrinsic frequency of inertia-gravity waves is the local inertial frequency). Accordingly, the phase lines of inertia-gravity waves are oriented close to the horizontal and can propagate significant horizontal distances from their source. Indeed, inertia-gravity waves observed in the lower stratosphere have been traced back to convection more than 1000 km away.

Tropical cyclones and hurricanes are also notable sources of gravity waves. Patterns of vertical velocity above these systems show a combination of short-scale gravity waves from individual thunderstorms and long-scale (~ 100 km horizontal wavelength) waves that are associated with the evolving eye wall and spiral rainbands. Numerical simulations have found

coherent spiral wave fronts above the convectively active cyclone rainbands. Notable variations in wave amplitude from these separate sources have also been linked to different stages of the cyclone intensification and decay cycle. The rotation of the wind around cyclones affects the wave propagation as well; the subsequent wave filtering, combined with different sectors of the storm featuring more active convection than others, creates considerable spatial variability in the gravity wave activity above cyclones.

Approaches

Numerical models have been utilized to study convective gravity waves, their generation mechanisms and to characterize the wave spectra. The advantage of numerical models is that they provide complete and consistent four-dimensional datasets that can be used to relate aspects of the waves to properties of the convection. Idealized approaches that systematically vary properties of the convection and/or the environment have also made valuable progress toward understanding and parameterizing these waves. However, models have their deficiencies, which pose challenges for studying this problem. Ideally, models should contain high enough resolution that convective structures are well resolved. Models that explicitly resolve moist processes, i.e., convection-permitting or cloud-resolving models, are preferable over models that parameterize convection. However, for studies of large areas and inertia-gravity waves such resolutions are not always achievable. Moreover, even at relatively short model grid spacings of about 1 km, convective updraft structures are not properly resolved, which makes the simulated convection and the waves it generates sensitive to horizontal resolution. For example, Figure 6 shows

a comparison of the wave spectrum from similar model simulations with 2 km and 125 m grid spacing; as the grid spacing is reduced the width of convective updrafts and the horizontal wavelength of the high-frequency waves also reduce. These sensitivities lead to changes in the spectrum and the shorter wavelengths are more likely to be filtered. Finally, the vertical resolution is also important and needs to resolve the vertical structure of the waves. This is particularly important in the stratosphere, where the vertical wavelength is usually smaller than in the troposphere due to the increased stability.

Observations are crucially important for studying convective gravity waves because they provide a true representation of the gravity waves in the atmosphere. Numerous platforms are used to study gravity waves including research aircraft, radiosondes, and remote sensing using radar and satellites.

Radiosondes, in particular, have been used extensively to describe the characteristics of gravity waves and their spatial and temporal variability. As a radiosonde rises, profiles of its three velocity components are determined from the change in position of the sensor with time; the horizontal position of the sensor is normally determined using Global Positioning System and the vertical position is determined from the measured temperature and pressure using the hypsometric equation. An example profile is shown in Figure 7, with the solid lines representing the horizontal atmospheric velocities (left and center) and the balloon's ascent rate (right). Gravity wave velocity perturbations are normally extracted from such a profile by defining them as deviations from smoothly varying profiles that are each defined using polynomials fitted to each profile; example background profiles are shown as dashed lines in Figure 7.

As radiosondes ascend they are advected horizontally as well, making the profiles shown in Figure 7 not true vertical profiles of the atmosphere. However, for waves with horizontal

wavelengths much longer than the horizontal motion of the radiosonde (i.e., inertia-gravity waves), the radiosonde profile can be assumed to approximate a vertical profile and vertical wavelength information can be determined through spectral or wavelet analysis. Moreover, different parts of the wave spectrum affect different variables more strongly than others; the horizontal velocity is more strongly influenced by inertia-gravity waves (i.e., low-frequency waves) and the vertical velocity is more strongly influenced by high-frequency waves. These properties, along with wave theory, are commonly exploited to determine the character of the inertia-gravity waves measured by radiosondes. The ascent rate perturbations provide a representation of the amplitude of the higher-frequency waves and newer techniques have been developed to use the ascent rate and temperature perturbations to determine the wave frequency as well. However, because the higher-frequency gravity waves usually have horizontal wavelengths shorter than the horizontal distance traveled by the radiosonde, the ascent rate profiles cannot be interpreted to represent the vertical wavelength of the gravity waves. Information about the horizontal wavelength and phase speed of the waves is combined in these profiles and is inseparable without additional assumptions or measurements.

Remote sensing applications like radar and satellite have also been used for studying convectively generated gravity waves. Vertically pointing radars have had success in measuring the frequency, vertical wavelength, and amplitude of gravity waves for many parts of the wave spectrum. Such platforms, however, have difficulty in inferring the horizontal wavelength of the gravity waves and can suffer from gaps in coverage due to variations in the atmospheric properties and finite radar range. Satellites offer much promise for determining statistics of gravity waves generated by convection through radiance

Figure 7 Gravity waves observed using radiosonde data (at 0300 UTC 27 November 1995, near Darwin Australia). Solid lines show the observed horizontal wind components (left and center) and the radiosonde ascent rate (right). The dotted lines represent background profiles used to define the wave perturbations. Adapted from Lane, T.P., Reeder, M.J., Guest, F.M., 2003. measurements that are used to infer temperature perturbations. Satellites have demonstrated their effectiveness in identifying large-amplitude wave events and their spatial structures, as well as the global statistics of wave activity. Like all observational platforms, however, satellites cannot measure the entire wave spectrum, and are restricted by the footprint of the sensor and the vertical structure of the weighting functions assigned to specific sensing channels.

Although observations do not suffer from the same approximations and sensitivities that models do, each measurement platform can usually only observe a part of the wave spectrum. Thus, approaches with multiple platforms or combined observational/modeling studies are normally required to fully characterize the wave properties. In addition, purely theoretical approaches using mathematical theory have been responsible for many advances in the understanding of gravity waves, their propagation, and generation.

Impacts

Gravity waves generated by convection have important impacts on the surrounding atmosphere. As described above, convective gravity waves in the troposphere can influence the morphology and longevity of convective systems and thereby play key roles in the dynamics of moist and dry convection.

The upper troposphere/lower stratosphere is an important region for convective gravity waves. The strong change in static stability at the tropopause contributes to the generation of waves by overshooting deep convection. The wind shear is often strong near the tropopause, and therefore the upper troposphere/lower stratosphere is normally a region of significant wave filtering. In particular, gravity wave breaking through critical level interactions near the tropopause generates turbulence and mixing as part of the wave dissipation process. The turbulence has been shown to transport water vapor and other constituents across isentropic surfaces, contributing to stratosphere–troposphere exchange. The turbulence associated with breaking convective gravity waves is also an important aviation hazard and is responsible for many commercial aircraft turbulence encounters.

Momentum transport associated with convective gravity waves also plays an important role in the dynamics of the middle atmosphere. For example, convective gravity waves contribute to the formation of the stratospheric quasi-biennial oscillation (QBO); it has been estimated that up to 80% of the forcing of the QBO originates from convectively generated waves (including convectively generated inertia-gravity waves). The importance of these waves, and the fact that most of the spectrum is unresolvable in global climate models, has motivated the development of parameterizations of the convective gravity wave source. These parameterizations have been informed by theoretical, observational, and numerical modeling studies of convective wave generation. The most common approach is to link the wave momentum flux to properties of the diabatic heating in the troposphere using

linear theory. Nonetheless, parameterization of these processes remains challenging because tropospheric convection is also parameterized, and the complicated nonlinear processes responsible for convective wave generation and dissipation are still not fully understood.

Introduction

Hydrology is the science that encompasses the study of water on the Earth's surface and beneath the surface of the Earth, the occurrence and movement of water, the physical and chemical properties of water, and its relationship with the living and material components of the environment. Ultimately, many hydrologic questions involve the transport of solutes, nutrients, energy, sediment, or contaminants, as well as the fluxes of water itself.

As a science, hydrology has both basic and applied aspects. The first relates to questions about the Earth system, and specifically about the role of water in natural processes, particularly as related to the Earth's biosphere. The second relates to using scientific knowledge to provide a sound basis for wise usage of water resources. The development of hydrologic science in recent years is based on both of these aspects, which are equally important and intimately linked.

Water is central to most natural processes. Water weathers, then transports sediment and solutes to lakes and oceans, thereby shaping the landscape. The land-based part of the Earth's water cycle is important for transporting carbon from the continents to the ocean. The high capacity of water for storing thermal energy and the large amount of heat required to change between solid, liquid, and vapor forms of water strongly influence the global energy balance. The distribution of atmospheric water and its regulation by oceanic and land-surface processes make it a central aspect of climate. Water vapor is the most important greenhouse gas. In short, life depends on water.

Hydrologic science has an important place in the field of water resources, especially freshwater resources, which are the subject of intense concern and study. In arid and semi-arid regions, the fair allocation and wise use of water are significant societal challenges, affecting relations between nations, states, cities, and individual users. As a global resource, water appears abundant. Locally and regionally it is often taken for granted. However, the twentieth century has witnessed a tremendous growth in the use of water, resulting in limits on both its availability, due to human exploitation, and its quality, owing to contamination.

Water Cycle

A fundamental concept of hydrology is the hydrologic cycle, which can be described at many different scales of space and time. At the global scale, the hydrologic cycle is the endless recirculatory process linking water in the atmosphere, on the continents, and in the oceans. We can think of this recirculatory process in terms of reservoirs or compartments that store water (e.g., oceans, atmosphere, glaciers, ice sheets, ground water) and the movement of water between them. Movement of water from one compartment to another can occur in any of the three phases. For example, the movement of water between the land surface and the atmosphere occurs in the vapor phase (evaporation and condensation), liquid phase (rain), and solid phase (snowfall).

Solar energy and gravity are the main forces driving the hydrologic cycle. The dynamic processes of water vapor

formation and transport of vapor and liquid in the atmosphere are driven largely by solar energy. Precipitation and the flow of water on and beneath the Earth's surface are driven primarily by gravity. Within partially dry soil, gravitational pressure and capillary forces are responsible for the movement of water.

The hydrologic cycle can be considered to start anywhere, but it is often convenient to consider atmospheric water first. The dominant hydrologic process involving atmospheric water is precipitation of water to the land surface. Condensation of water from the atmosphere to the land surface (e.g., dew, frost) and fog deposition can be important locally, in the absence of precipitation. Precipitation that reaches the land surface as snow or ice can be retained on vegetation and subsequently evaporate or fall to the ground, accumulate in seasonal snow-packs, and later melt or evaporate or accumulate in glaciers, ice caps, or ice sheets. Water is also lost from glaciers and ice caps by evaporation and melting; pieces of ice can also break off from the edges of glaciers and ice sheets (this is known as calving) and be returned directly to the ocean, in the form of icebergs. A portion of rain or snowfall can be retained temporarily on vegetation surfaces, and subsequently evaporate or fall to the ground. Rain or snowmelt can also collect in surface depressions, enter into the soil (infiltration), or flow as runoff over the land surface into small rivulets and ultimately into larger streams, lakes, and rivers. Water that infiltrates into the soil can also follow different paths. Some returns to the atmosphere by evaporating from the soil or being transpired by plants (transpiration), the sum of which is termed evapotranspiration. The remaining water continues to move downward through the soil and recharges the saturated portion of the subsurface, becoming groundwater. Ground water discharges into streams and rivers, or directly to the ocean. Water evaporates from the surface of the oceans and thereby replenishes the water in the atmosphere.

Much effort in hydrology goes toward estimating the amounts of water in the various storage compartments and the magnitudes of the various flows to and from these compartments at local, regional, and global scales. Nearly 97% of all water on the Earth is stored in the oceans, while only about 0.001% is stored in the atmosphere. Fresh water accounts for about 2.5% of the total storage, 70% of which is contained in the two polar ice sheets and 30% is found in ground water. Only about 0.4% is found in glaciers and ice caps. The fresh water in lakes, streams, rivers, and marshes represents only 0.26% of all fresh water and 0.008% of all water on Earth. That is, if the Earth's ocean were represented as a 16 l (4 gallon) bucket, the fresh water fraction would be equal to a little over 1 ml ($\frac{1}{4}$ teaspoonful).

Another useful concept for enumerating reservoirs and the flows of water through them is residence time, which is a measure of how long, on average, a molecule of water spends in that reservoir before moving on to another reservoir of the hydrologic cycle. For a system at steady state, i.e. with inflow and outflow the same, residence time is equal to the size of the reservoir (e.g., in m^3) divided by the flow through the system (e.g., in $\text{m}^3 \text{ yr}^{-1}$). Water in the oceans has a residence time approaching 3000 years, less than half of the residence time for ice sheets, while in the atmosphere it has a residence time of only 0.02 years or about 8 days; the residence time in rivers is 0.05 years or about 17 days.

Most of hydrology deals with scales smaller than global; however, the same concepts of fluxes and reservoirs apply. A catchment is an area in which water falling on or flowing across the land surface drains into a particular stream or river and flows ultimately through a single point or outlet. Thus a catchment is defined relative to a specific location and includes all of the land area that drains to that point; i.e., it can be considered to catch the water that flows past that point. Clearly, then, any number of catchments can be defined for a particular river (corresponding to any location along the river). Some special locations of interest for defining catchments are points corresponding to dams, stream gauges, cities, and a river's mouth. Ground water reservoirs (aquifers), on the other hand, are defined by subsurface geologic structure. Aquifers, or water-bearing formations, are bounded by material of low permeability, i.e., material with a very small ability to transmit water.

Precipitation

Precipitation is the deposition of liquid water droplets and ice particles that have formed in the atmosphere and grown to a size sufficient to fall to the Earth's surface by gravity. Precipitation is classified according to the phase it is in when it reaches the ground, i.e., solid (snow, sleet, and hail) or liquid (rain and freezing rain). Other deposition processes (e.g., direct deposition of dew and fog), though generally small, can however be important in terms of chemical fluxes (e.g., acidic fog).

Most of the precipitation falling over North America originates from the bordering oceans, even in the interior of the continent. However, over the Amazon basin, a significant fraction of the precipitation is derived from within-basin evapotranspiration. In other continental basins, local evapotranspiration does have some influence on local precipitation, but most of the precipitated water must be transported significant distances across the continents from the oceans.

Average precipitation over the continents is extremely variable geographically, reflecting the influence of a number of important physiographic factors. First, precipitation increases with elevation owing to orographic cooling. Second, precipitation is typically higher on windward than on leeward sides of mountain ranges. Third, precipitation tends to drop off as air masses move further inland, away from the ocean. Fourth, the temperature differences between adjacent land and ocean influence moisture transport. Fifth, prevailing wind direction has local to regional effects.

Global average precipitation is about 1000 mm yr^{-1} . In the continental US, average annual precipitation ranges from about 40 mm yr^{-1} at Death Valley, California (in the Mojave Desert), to over 3000 mm yr^{-1} in parts of the Pacific Northwest. In the Atacama Desert of northern Chile rainfall is infrequent, averaging under 1 mm yr^{-1} .

Rainfall and snowfall are measured at a point by collectors of very simple construction. Essentially, any receptacle with a reasonable opening can serve to estimate the precipitation per unit area. In the US, the standard gauge has a 20 cm diameter opening. Wind is probably the single most important factor in rain gauge accuracy. Updrafts resulting from air moving up and around the instrument reduce the catch, which has led to the

development of elaborate shields to mitigate wind effects and detailed correction procedures.

In a few areas, radar is also used for precipitation measurement, although rain gauges are generally required for calibration. Radar emits electromagnetic energy in narrow bands, which upon hitting precipitation is partially absorbed, scattered, and reflected. Some of the reflected energy returns to the transmitter, and the attenuation of the signal indicates the intensity of rainfall. In principle, the same method could be used for snowfall.

Snow accumulation at a point is more accurately measured, either in situ by snow pillows equipped with pressure transducers or manually. Snow accumulation is reported in terms of equivalent water depth rather than snow depth, the proportionality factor being the density. Snow accumulation can also be measured from aircraft in terms of the extinction of gamma or other types of radiation. Satellites are used for estimating snowpack depth and areal coverage. A combination of visible and infrared signals are used to extract snow-covered area. Over flat terrain, passive microwave signals indicate snow water equivalent. Because much snow falls in heterogeneous terrain and is thus not uniformly distributed, accurate measurements of snow water equivalent remain a major challenge. Snow measurement networks in the western US consist of index sites, for which correlations with streamflow have been developed. They do a relatively poor job of providing direct estimates of snow volume.

Snowmelt plays a major role in the hydrology of midlatitudes, as many rivers originate in mountains where snow dominates the precipitation. In contrast to rainfall, snowfall has a delayed effect on river flow and hydrology. Accumulation occurring during winter months becomes all-important during spring runoff, which provides much of the streamflow, ground water recharge, and soil moisture for wide areas of the Earth. Melt waters can also cause serious floods, particularly when compounded with spring rainfall.

Catchment

Much effort in hydrology focuses on water balances at the scale of a catchment, be it a 1 km² headwater basin or a 100 000 km² regional basin. Hydrologists often think of a catchment as functioning like a group of reservoirs that store and release water. Precipitation and snowmelt are the inputs to the catchment reservoir, and evapotranspiration and runoff are the outputs. Integrating the various processes that affect runoff involves quantitative partitioning of the different fluxes and reservoirs into downstream fluxes and reservoirs. For example, a fraction of precipitation is intercepted by vegetation, with the remainder falling to the ground. Intercepted rain and snow then either evaporates or eventually falls to the ground. Snow on the ground partitions between snowmelt and sublimation. Rainfall or snowmelt reaching the ground either infiltrates or runs off, depending on the infiltration capacity of the soil. A portion may flow downstream in the subsurface and reemerge at a lower point in the catchment. Much infiltrating water may eventually be transpired by plants or evaporated, though some will travel downward sufficiently far to enter, or recharge, a ground water aquifer. Of

all these quantities, surface runoff in streams and rivers, or discharge, is most often measured.

Discharge is estimated by continuously measuring the stage, or height of a stream at a point using a pressure transducer or a mechanical float. This point measurement is then related to the volumetric discharge through a calibration, or rating, curve, which is developed by measuring the volumetric discharge at the gauged point for many different stages. A time series graph of discharge is commonly referred to as a hydrograph.

A streamflow hydrograph is often defined in terms of two components, quickflow and baseflow. Separation of a hydrograph into two components suggests that water is being routed through two different storage reservoirs. During and after rainfall and snowmelt events, water moves through the catchment into the stream channel and the discharge increases (quickflow). The resulting peak in the hydrograph is generally defined as a flood, regardless of whether the river actually leaves its banks and causes damage. Background discharge between floods (baseflow) is supplied by inflow of ground water, which may lag the occurrence of precipitation by days, weeks, or even years.

Water flowing across the ground surface is termed overland flow. For this to occur, water must accumulate at the surface rather than infiltrate into the soil. This happens for three main reasons: (1) the catchment surface may be nearly impermeable owing to the presence of exposed bedrock or pavement; (2) the instantaneous rate of infiltration through the pervious surface may be exceeded by the instantaneous rate of rainfall (or snowmelt) onto the catchment surface, causing ponding of water at the surface, and (3) the catchment soil upon which the rainfall is precipitated may be saturated to the soil surface, causing ponding because the precipitated water cannot infiltrate into an already saturated soil. Overland flow in catchments is one of the most rapid paths that water can follow to the stream channel.

Water that has infiltrated the soil surface continues to be influenced by gravity, so that it percolates downward through the soil profile. In general, the ability of the soils and rocks of a catchment to conduct water (hydraulic conductivity) decreases with depth; water percolating downward has thus been observed to back up, causing local areas of saturation in the soil. In these instances, water may move laterally toward a stream by a process known as shallow subsurface stormflow. Some of the water in subsurface stormflow moves at a relatively slow pace through the soil and contributes to the baseflow of streams, particularly during wetter winter and spring periods. Subsurface stormflow also may occur quite rapidly along preferred flow pathways or macropores (e.g., soil cracks, old animal burrows, and decayed root channels).

Vadose

In most areas, the water table is some distance below the ground surface. Between the ground surface and the water table is a region in which the pore spaces of the rock or soil may be partly filled with air and partly with water. This region is referred to as the unsaturated zone or vadose zone, and water in this zone is referred to as soil moisture. Hydrologists want to be able to describe the amount of water in the unsaturated zone and

fluxes through the zone for two main reasons. First, ground water recharge occurs through this zone. Second, most terrestrial plants extract water from the vadose zone. Plants wilt when soils become too dry because the tension forces holding the water in the soil are too great to allow the plants access to the water. Related to the water balance of plants is the practice of irrigation in agriculture, which accounts for about two-thirds of global water use. Understanding the movement of soil water, its uptake by plants, and its loss through evapotranspiration and recharge to the groundwater system is essential in this regard.

Hydrologists have traditionally recognized three divisions within the unsaturated zone: the capillary fringe, the intermediate belt, and the belt of soil water. The capillary fringe is a zone in which the pressure is less than atmospheric, overlying the zone of saturation and containing capillary interstices, some or all of which are filled with water that is continuous with the water in the zone of saturation but is held above that zone by capillarity forces acting against gravity. That is, the capillary fringe is a saturated zone above the water table where water is affected by capillary forces. Above that is a zone of soil water from which water is discharged to the atmosphere by the action of plants or by evaporation. For the most part, plants extract water from a portion of the soil near the surface (the 'root zone'). Depending on the depth of the vadose zone and the plant, roots may lie only in the upper part of the vadose zone, or extend into the water table. For example, most grasses have roots extending only a few centimeters to tens of centimeters, whereas some trees in semi-arid regions have roots that extend through vadose zones that are tens of meters thick and reach the water table. The volumetric moisture content (volume of water per bulk volume of soil sample) in the capillary fringe is the saturation value. In other words, the pores are completely filled with water. As water drains or is withdrawn by plants, soil moisture content decreases from saturation to a fairly constant value, termed the field capacity.

Rates of removal of water from the unsaturated zone by evapotranspiration are controlled by a number of factors, including the wetness of the soil itself. If a vegetated surface is supplied with plenty of water (e.g., a well-watered lawn), evapotranspiration will be controlled by atmospheric conditions, e.g. solar radiation, wind speed, and humidity. That is, evapotranspiration will proceed at the maximum rate (potential evapotranspiration). As a soil dries, evapotranspiration will proceed at the potential rate for some time, but ultimately the rate will drop. As water is pulled from the soil near a plant root, the moisture content in the soil surrounding the root decreases. In order to maintain a steady flow of water to the plant root, the plant must exert ever greater suction (ever greater negative capillary pressure heads). At some point, the plant cannot sustain this battle with a drying soil and the transpiration rate falls below the potential rate.

Most plants have openings (stomata) on their leaves to allow them to take up carbon dioxide from the atmosphere. When the stomata are open, plants transpire water. Unlike evaporation, transpiration is not controlled solely by physical conditions because plants regulate the rate at which water is released in transpiration in a manner that varies by plant type and ecological conditioning. Of the water taken up by plant roots, most is transpired through the stomata. A few percent is concerted to biomass through photosynthesis. Hence, to first

order, the water taken up by the roots is converted to vapor and lost to the atmosphere. The degree of stomatal restriction varies considerably across plant species and even throughout the year for a given species.

Ground Water

The largest accessible fresh water reservoir for human exploitation is ground water, or water that is present in the fractures and interstitial spaces in subsurface geologic materials. In contrast to the vadose zone, in ground water the void spaces are completely filled with water. An aquifer is a saturated geological formation that contains and transmits significant quantities of water under normal field conditions. 'Significant' is a vague term, but the implication is that aquifers are formations that can be used for water supply. Many aquifers are unconsolidated materials, mainly gravel and sand. Examples of this type of aquifer include those in coastal plains and intermontane valleys. Limestones, partially cemented sandstones and conglomerates, and permeable volcanic and igneous rocks are also important as aquifers.

An aquitard is a formation of relatively low permeability, and includes both formations that contain water but do not transmit significant quantities (e.g., clays and shales) and formations that neither contain nor transmit significant quantities of water (e.g., unfractured crystalline rocks).

Aquifers are classified according to hydraulic conditions as well as type of material. Ground water by definition refers to water in the saturated zone of the subsurface; one type of aquifer is an unconfined or water table aquifer. Deeper in the soil profile, saturated conditions prevail (the saturated zone). The water table is defined as a surface of zero (gauge) pressure within the subsurface, and separates the saturated and unsaturated zones. Water will flow into an excavation or well up to this level; the water table is equivalent to a free surface. An aquifer with the water table as the bounding surface at its top is an unconfined aquifer.

The second type of aquifer is a confined or artesian one. This is found when permeable material (the aquifer) is overlain by relatively impermeable material. The water in a confined aquifer is under pressure and, in a well penetrating the aquifer, will rise above the top of the aquifer. The height to which water rises in a well defines the piezometric surface, or pressure of water in the aquifer.

In areas where the water table is sufficiently close to the ground surface, ground water levels are influenced directly by transpiration. During the day, when transpiration is high, water movement is upward from the water table and the level declines. At night, transpiration is reduced, groundwater flows laterally from locations relatively unaffected by direct transpiration effects, and the water table recovers.

Recharge to aquifers can occur from direct infiltration of rainfall or snowmelt past the root zone and to the water table. Water can also seep from surface water bodies, such as rivers, ponds and lakes, into the ground. Artificial recharge (recharge induced by activities of people as opposed to that which occurs naturally) can be implemented by introducing water into recharge wells or by routing water into infiltration basins in permeable material.

The specific yield is a hydrologic parameter that determines the response of the water table to changes in inputs and outputs. In the case of an increase in evapotranspiration, the change in water table level may be fairly uniform over a given area, although variations will occur due to the lateral movement of groundwater and spatial variations in evaporation rate and vegetation. Pumping a well has a different level in the pumping well, or in observation wells nearby, is referred to as drawdown. The amount of this drawdown will decrease as one moves away from the pumping well, and the pattern produced is called a cone of depression because of its characteristic shape.

Integration

The need for an integrated understanding of water cycles and linked chemical cycles is critical for a number of reasons. For example, a quantitative understanding of how ground water recharge changes with precipitation in a variable or changed climate requires an understanding of how catchment processes respond to translate precipitation into recharge. Understanding how evapotranspiration and ecosystem functioning respond to change in land use depends on how water and nutrient fluxes

change. Hydrologic science is at the center of many pressing issues in other natural sciences.

This article is a revision of the previous edition article by G Wang, G S Jenkins, volume 2, pp 633–640, © 2003, Elsevier Ltd.

Synopsis

Deserts cover about 35% of the land surface area of the world and are typically located between and astride the Tropic of Cancer (35° N) and the Tropic of Capricorn (35° S). About 20% of the world's population resides in this geographic region. The location of this global arid zone is primarily the result of the semi-permanent high-pressure cells that dominate this region along with such other factors as rain-shadow effects, continentality or remoteness from moisture sources, upwelling of cold currents that suppress the development of precipitation, and the nature and direction of the prevailing winds. Most deserts exhibit a combination of the above factors. Desertification refers to land degradation in the global arid zone owing to a series of complex climatic, biophysical, and anthropogenic factors and became a major global topic during the severe drought of the Sahel region in northern Africa in the 1970s. Desertification has been erroneously represented as the irreversible march of the desert and is now believed to result primarily from the degradation of arid ecosystems largely because of human induced factors along with natural climatic oscillations and drought cycles.

Introduction

Deserts (arid lands/drylands) constitute about 35% of the land areas of the world and are typically characterized by rainfall scarcity, higher temperatures and evapotranspiration, lower humidity, and a general paucity of vegetation cover. A unique combination of atmospheric, geologic, and geomorphic conditions is responsible for the formation of deserts primarily between the Tropics of Cancer and Capricorn (Figure 1). Compared to humid lands, the relative importance of desert atmospheric and geomorphic processes and the magnitude and frequency of their operation is rather distinctive. Arid lands

comprise the most widespread terrestrial biome on Earth and are home to over 20% of the world's people. In the twentieth century, a combination of natural and anthropogenic factors gave rise to the concept of desertification – first as a rather simplified 'march of the desert' into bordering semiarid regions, and then recently as a more complex phenomenon that includes both natural and anthropogenic causes, the latter primarily the consequence of increased population numbers in the semiarid regions of the world. The distinctive natural environment in arid lands, coupled with the growing human populations in drylands, is one of the primary reasons behind the recent upsurge in the global study of deserts.

Figure 1 Global distribution of deserts. Reproduced from Goudie, A.S., 2002. *Great Warm Deserts of the World*. Oxford University Press, Oxford.

Deserts of the World

Drylands of the world can be either classified as arid, based on climate or desert, based on surface characteristics (landforms, vegetation, etc.). For the purpose of this review, we will use the climatic classification adopted by UNESCO in 1979. Deserts thus can be classified as (1) semiarid (precipitation less than 500 mm); (2) arid (precipitation less than 250 mm); and (3) hyperarid (precipitation less than 25 mm). Approximately 16% of the global arid zone is semiarid, 15% arid, and 4% hyperarid. The division between the three is somewhat arbitrary and based on limited climatic data owing to the fact that there are large variations in annual precipitation regimes and that natural and anthropogenic activities have shifted those boundaries. Africa contains the greatest proportion of the global arid zone at about 37%, while Australia is the most arid continent, with about 75% of the land area being arid or semiarid. Contrary to public opinion, sand dunes and sand seas (ergs) are not the dominant landform type in deserts, although dunes cover about 40% of the surface area of Australia (most are stabilized, relict dunes), constituting 38% of the world's dune fields. A recent landform map of North Africa (mostly the Sahara Desert) produced through moderate resolution imaging spectroradiometer, indicated that the two most dominant landform types were stone pavements (hamada, serir, reg, desert pavement) at about 25% cover, followed by sand seas (ergs) at about 20%. On the other hand, the North American arid zone includes extensive areas of alluvial fans, mountains, desert flats, playas, and arroyos, while sand dunes and sheets constitute less than 5% of the arid zone.

There are a number of reasons for the global arid zone. The majority of the world's deserts are subtropical in distribution, covering about 20% of the Earth's land surface and located between the Tropic of Cancer (23.5° N) and the Tropic of Capricorn (23.5° S). The strong subsidence of air in these regions is largely the result of the descending branch of the Hadley cell, which causes air at the surface to be hot and dry. These are the locations for some of the most famous deserts in the world such as the Sahara Desert, the Rub'al Khali in the Arabian Peninsula, the Thar desert of India and Pakistan, the Kalahari Desert in southern Africa, the Sonoran and Chihuahuan Deserts of North America and the Australian deserts – Simpson, Gibson, Great Sandy, Tanami, and the Great Victoria (Figure 1). These deserts typically exhibit very high insolation values, very low humidity, very high evapotranspiration rates and extreme spatially and temporally variable precipitation regimes, with occasional heavy, short-lived thunderstorms, largely associated with the seasonal movements of the intertropical convergence zone (ITCZ). Another type of desert is formed when moisture is prevented from reaching continental interior locations because of either the distance from water bodies or the presence of mountain ranges. Examples of continental interior deserts include most of the midlatitude Asian deserts such as the Taklimakan and the Gobi Desert in China, the KaraKum deserts in Kazakhstan and Uzbekistan, and parts of the Great Basin and the Colorado Plateau in the United States. For example, moist air masses that originate around Scotland (wet) can move over Poland (moist) and will most likely be dry by the time they cross the Volga River on their way to central Asia. Other deserts owe their

existence because of their location on the lee side of major topographic barriers such as the Mojave Desert being on the rain shadow of the Sierra Nevada Mountains and the Transverse Ranges of southern California. Parts of the Great Basin and the Colorado Plateau in the United States are also considered rain-shadow deserts as well as the Patagonian Desert in Argentina. The north–south orientation of the Great Dividing Range in eastern Australia also contributes to the lee side aridity of the Simpson Desert, as easterly trade winds are prevented from bringing their moisture past the Great Divide. Deserts are also formed on the western coastline regions of continents, where the upwelling of cold, ocean currents, suppresses any precipitation potential. Other climatic conditions include low sea-surface evaporation, high atmospheric humidity, low annual temperature ranges, and extremely low rainfall amounts. Warm air as it moves over these cool waters is chilled/condensed (only a thin layer is affected) forming mostly fog and dew, which for many years is the only source of moisture for plants. Examples include the Namib Desert, located mostly in Namibia (Benguela Current), Baja Deserts in Mexico (California Current), the Atacama Desert of Chile and Peru (Humboldt or Peru Current), and smaller arid zones off the coasts of Mauritania, Somalia, and NW Australia. The Atacama Desert of northern Chile is considered 'the driest place in the world,' with less than 10 mm of annual precipitation, and runs roughly about 4000 km from north to south. In addition, winds in this region typically blow parallel to the coast and thus inhibit the eastern movement of moist air from the Pacific to the Atacama region. In summary, the general causes of aridity and hence the presence of deserts in the world can be summarized as (1) atmospheric stability (subtropical highs/Hadley cell circulation); (2) rain-shadow effects; (3) upwelling cold currents off west coasts; (4) prevailing winds parallel to coasts; and (5) remoteness from moisture sources (continentality). It should be noted that most deserts are arid because of a combination of the above five factors.

Desert Hydroclimatology

Clear skies, lack of cloud cover, and low water vapor content are responsible for the high persistent temperatures that characterize most desert environments (variations discussed under microclimates) with maximum temperatures commonly between 45 and 50 °C. Subtropical deserts tend to experience hot summers and cool winters, while midlatitude deserts tend to have hot summers but very cold winters. Annual temperature fluctuations tend to be highest in midlatitude deserts, while diurnal temperature changes can be extreme in all desert environments, except the cool, coastal deserts (Figure 2). During the daytime, the incoming solar radiation heats up surfaces very rapidly causing the temperature (sensible heat) to rise. During the night, when terrestrial long-wave radiation dominates the surface energy budget, the surfaces cool very rapidly owing to the fact that clear, dry, and cloudless skies cannot trap the outgoing terrestrial radiation, and thus the very large diurnal temperature fluctuations. A >30 °C range is very typical in subtropical deserts and a 50 °C diurnal range has been reported from dark, basaltic rocks in the central Sahara Desert. The breakdown of rocks as a result of volumetric

Figure 2 (a) January and (b) July long-term observed temperature. Temperatures greater than 25 °C are shaded. The darkest shading represents temperatures greater than 30 °C.

changes from thermal expansion and contraction has been proposed as one of the physical weathering processes in hyperarid deserts (most likely it is the individual minerals that are found in rocks that will respond to these thermal changes, leading to granular disaggregation. Unequal thermal expansion of the dominant minerals is the controlling factor).

Deserts typically receive less than 1 mm per day rainfall when averaged on an annual basis (Figure 3). Precipitation in deserts typically occurs in short durations but at high intensities, with low overall amounts, at irregular intervals, often with a strong seasonal bias and usually with a very large interannual variability. Enhanced precipitation owing to orographic (mountain) effects is especially prominent and has a strong impact on the spatial distribution of flora and fauna. Storms typically form as discrete convective cells and are unlikely to affect the entire drainage network within a desert – hence storms have low frequencies and high magnitudes and are

typically discontinuous in space and time. The rain falls on ground with a sparse or nonexistent vegetation cover, which is irregular in its distribution and especially adapted to collect rainfall. Interception rates are low and highly variable and rapid direct evaporation of excess surface water is characteristic. Evaporation rates from exposed surfaces are high in subtropical deserts, particularly during the summer months. Additionally, infiltration is largely controlled by the bare surface characteristics, which range from sands and alluvium to organic crusts and from stone (desert) pavements to duricrusts (a product of processes acting within the zone of weathering to cause the accumulation of iron and aluminum oxides, silica, calcium carbonate, or less commonly gypsum), such as calcrete (caliche/calcium carbonate).

Most runoff in deserts occurs as overland flow (Hortonian overland flow) with vegetation type and densities as well as surface and subsurface (soil) characteristics controlling the

Figure 3 Annual precipitation rates for areas that receive less than 2 mm day^{-1} of rain. The darkest shaded regions receive less than 0.5 mm day^{-1} of rain.

intensity and duration of overland flow. Most overland flow is ephemeral, lasting only hours or days. Desert streams exhibit flashy hydrographs with short recessional limbs because of the predominance of overland flow, and seepage and transmission losses into the underlying alluvial stream beds are common, thus the importance of groundwater in providing moisture to plants and people. Although water paucity is the norm in deserts, there are water supplies that when used wisely, can sustain people and ecosystems in the global arid zone. Some of these sources are as follows: (1) perennial and ephemeral rivers, (2) wadis and arroyos, (3) groundwater from shallow (alluvial fans) and deep aquifers (mostly fossil aquifers), (4) lakes and playas, (5) fog, dew, and snow, (6) desalination plants, and (7) dams and reservoirs. The hydrological conditions in deserts leads to less weathering and leaching and hence soils tend to be shallow with coarse textures, high aeolian content, and retain many soluble substances (such as carbonates and salts). Soil pedogenesis (formation) takes a long time and paleosols (ancient soils) are rather common in many global deserts and can be used as proxy data for past climates.

Deserts also exhibit certain geomorphic processes and landforms that are rather unique or operate more favorably than in other environments. Some of these attributes include a rather open and exposed landform assemblages in part because of the limited vegetation cover with high and frequent changes in relative relief, many superimposed landforms and sediments from previous geologic periods – hence a veritable laboratory for studying past climates (such as lake cores and sediments), and the greater efficacy of wind as a geomorphological agent of erosion and deposition (hence the vast expanses of sand dunes and sand seas), and dust entrainment and transport.

Desert Microclimates

Microclimates are significant within deserts because they offer less arid conditions for plants, animals, and humans. Some

examples include (1) modification of relative humidity – mostly by nocturnal radiation and the shade effects or mixing with cooler air masses. The drops in temperatures increase the relative humidity of the air and the chances of moisture condensation as either fogs or dew (Namib Desert – up to 150 mm of moisture has been calculated). This process is vital for the survival of rich desert ecosystems such as in the Namib, Atacama, and Baja California deserts; (2) reduction of temperature extremes – any shade-giving object produces direct reduction of air temperatures in the arid lands because of the importance of the direct radiation component in the cloud-free atmosphere; and (3) reduction of wind speeds – shelter from wind movement reduces the amount of moisture loss from evapotranspiration – vegetation is sometimes used as a wind break; however, its competition for soil moisture may reduce crop yields close to the barrier (economic factors to be considered).

The single most important microclimate is provided by mountains, which offer the maximum modifications with respect to overall climatic variables. These include the reduction of air temperatures with altitude, shade effects (plants can grow which themselves provide shade – pinyon–juniper trees), increased chances of precipitation (orographic effects), as well as air drainage among the basins and the ranges (peaks and valleys), which can ameliorate diurnal temperatures and humidity.

Desertification

Desertification refers to land degradation in the global arid zone resulting primarily from various anthropogenic (human land use) and biophysical factors (climatic variations). In 1978 at the first UN Conference on Desertification (UNCOD) the following definition was proposed “Desertification is the diminution or destruction of the biological potential of the land which can lead ultimately to desert-like

conditions.” Desertification ultimately reduces the sustainability of arid lands whereby agriculturally productive lands become barren and thus prone to wind and water erosion and other forms of land degradation. For example, UNCOD estimates that moderate desertification can lead to a 10–25% drop in agricultural productivity. Contrary to public opinion, desertification does not refer to the expansion of deserts – although the margins of deserts are known to oscillate north and south owing to natural perturbations in climate and the resulting response of ecosystems. Desertification has occurred because desert ecosystems, which cover over one third of the world’s land area, are extremely vulnerable to overexploitation and inappropriate land use, compounded by poverty, political instability, deforestation, overgrazing, and wasteful irrigation practices. According to UNCOD, over 250 million people are directly affected by desertification. In addition, some 1000 million (or 1 billion) people in over 100 countries are at risk. These people include many of the world’s poorest, most marginalized, and politically weak citizens.

Another way for looking at desertification is to analyze the ‘5Ds’ specifically and these include drylands, drought, desiccation, degradation, and desertification. ‘Drylands’ are the world’s arid lands (semiarid, arid, and hyperarid) that are inherently prone to natural perturbations throughout geologic time; ‘drought’ is a short-term (a few years) and natural decline in precipitation and desert ecosystems and economic systems (people) adapt to those changes and eventually there is full recovery during moister times; ‘desiccation’ is drought conditions that lasts over an extended period of time (such as decadal), and has an adverse impact on both natural and cultural ecosystems with some systems never recovering or needing many years to reestablish (such as certain plant species or transborder migration of peoples); ‘degradation’ is the end result of drought and desiccation with the land losing its agricultural productivity leading to water and wind erosion, salinization on one hand, and the loss of the natural vegetation as a result of overgrazing, firewood collection, and groundwater

removal on the other; and ‘desertification’ would then be the ultimate end of this cycle whereby desert conditions overwhelm the whole ecosystem. Although the system above seems like a positive feedback scenario, land degradation and desertification are more likely to operate on a negative feedback method, whereby eventually the system will revert back to its original position albeit having crossed a number of thresholds and experienced a few positive feedbacks during its cyclical journey.

Desertification and the Sahel

It was the severe droughts beginning in the late 1960s in the Sahel (the areas immediately to the south of the Sahara Desert) and its subsequent socioeconomic consequences that enabled desertification to be firmly established within the global community as one of the most consequential environmental events of the late twentieth century (Figure 4). We will use the Sahel as a case study since it contains all the variables necessary for understanding global desertification. Three interrelated factors contributed to the environmental disaster of the Sahel:

1. Climatic – the Sahel is a transitional geographic region between the dry, desert climates of the Sahara and the moist and humid savanna environments to the south, with significant variability in the spatial and temporal distribution of precipitation. A short rainy season associated with the northward movement of the ITCZ is separated by long stretches of dry and dusty weather. Any prolonged interruptions in the arrival of the rainy season can lead to drought and desiccation. This transitional climatic zone is thus highly susceptible to both long-term and short-term climatic oscillations, and has undergone major climatic swings since the Last Glacial Maximum at about 18 ka. During the last Ice Age (Wisconsin Age in North America), the Sahel experienced an intense arid period characterized by major dune building episodes and dust deposition, followed by a much cooler and wetter period from 11 to 8 ka (the period of major rock art in the Sahara with petroglyphs

Figure 4 Sahel precipitation anomalies 1900–2012. Reproduced from <http://jisao.washington.edu/data/sahel/>.

of crocodiles and giraffes painted in rock shelters and caves). This period was then followed by a brief arid episode and then another wetter than present period from 7 to 5 ka. Since 5 ka, aridity has slowly returned to the Sahara–Sahel, as the subtropical high-pressure cells assumed their current position, with today's hyperarid central Saharan core region well established by 2 ka. Desert margins, such as the Sahel, are thus very prone to extreme climatic variability, with many decades of good wet years followed by short to decadal length drought periods. The natural vegetation is rather resilient and adapted to these chronic environmental stresses and will typically recover after brief or even decadal perturbations in rainfall regime. However, twentieth century changes in land use and land cover from increased population pressures on the landscape have altered the natural ecosystem cycle (more below). Rainfall in the Sahel appears to be strongly influenced by the combined effects of North Atlantic Oscillation (NAO) and the El Niño–Southern Oscillation (ENSO). The interannual variability in the position of the northern boundary of the Sahel (southern boundary of the Sahara), as represented by the 200 mm isohyet, can be explained in large measure by changes in NAO and ENSO. Various studies have indicated that up to 75% of the interannual variation in the extent of the Sahara Desert is accounted for by the combined effects of NAO and ENSO. The drier years in the Sahel tend to be associated

with warm sea surface temperatures in the southern oceans and Indian Ocean, and anomalously cold sea surface temperatures to the west of the continent. Two recent studies have advanced our understanding of the physical factors controlling long-term, persistent drought in the Sahel. One study has shown that the Sahel drought of the last 40 years was likely initiated by a change in worldwide ocean temperatures (multidecadal variations in sea-surface temperatures (SSTs)), which reduced the strength of the African monsoon, shifted the ITCZ, and was exacerbated by land–atmosphere feedbacks through natural vegetation and land cover change (Figure 5). Land use changes by humans may have also played an important role. Another study, using laminated sediment cores from a lake, found that the recent Sahelian droughts of the 1960s and 1970s, are characteristic of the monsoon and are linked to natural variations in Atlantic SSTs and, furthermore, these droughts have occurred many times during the past three millennia, and although the most recent multidecadal drought of the 1970s had widespread ecological, political, and socioeconomic impacts, the climatic oscillations of the past 3000 years are capable of much more severe and longer drought cycles. In summary, large-scale atmospheric circulation changes brought on by multidecadal oscillations in global sea-surface temperatures, seem to be the primary biophysical mechanism (in addition to the human

Figure 5 Complex feedbacks. The recent Sahel drought was likely initiated by a change in worldwide ocean temperatures, which reduced the strength of the African monsoon, and was exacerbated by land–atmosphere feedbacks through natural vegetation and land cover change. component discussed later) that contributes to desertification, and that their length, severity, and origin can be traced back at least 3000 years.

2. Geomorphic – underlying the natural surface of the Sahel is a mantle of relict dune sands (ergs) from the Pleistocene presently stabilized and anchored by the vegetation (Figure 6). The removal of the vegetation cover by either anthropogenic or natural causes will lead to a significant increase in aeolian activity and in sand/dust storms. Owing to the nature of the aeolian sand, the topsoil is thin, with shallow root systems, and the water table very low and highly susceptible to increases in water use as well as to pedogenic carbonate formation (which can affect water quality and translocation of nutrients). Aeolian activity is further enhanced in this region by the presence of many winds such as the trade winds, Harmattan, and Khamsin, and other convective mesoscale systems. The Harmattan, is a dry and dusty Sahelian tradewind that sometimes extends all the way to the ITCZ. It blows south from Sahara into the Gulf of Guinea from November to March. Over the Sahara, it picks up fine dust particles some of which might end up in the Caribbean and even North America. Since sediment transport varies with the cube of the wind speed, a slight increase in wind speed will result in a threefold increase in sand and dust transport. Reactivation of some of the

stabilized Sahelian dormant/relict dune systems has been the result of both increased population pressure in the region (stabilized dunes provide a richer plant cover for grazing and firewood gathering, and are also easier to cultivate), and to long-term decadal drought owing to the atmospheric perturbations from global sea-surface temperature changes.

3. Anthropogenic – factors such as overgrazing and conversion of woodland to agriculture are among features that have been proposed as human-induced causes for desertification. Persistent, decadal drought, and desiccation leads to increased pressure on land use and land cover, compounded by a concomitant increase in population (from high birth rates, immigration, and population movements because of conflict). The demand for water and energy also soar putting additional pressure on people and governments. The human-induced stresses lead to such manifestations of desertification as (1) soil erosion and salinization (and/or waterlogging) as a result of the population exceeding the environmental thresholds of agricultural sustainability owing to overgrazing, overcultivation, deforestation, etc.; (2) wind erosion leading to increased frequencies of dust and sand storms (including loss of topsoil); (3) drawdown in groundwater, wells, and diminished use of dams and other irrigation schemes; (4) introduction of exotic species;

Figure 7 Schematic mechanism for the enhancement of desertification through biosphere-atmosphere interactions.

(5) war and civil unrest with all its socioeconomic ramifications – the Sahelian population is doubling every 20 years. All the above ultimately changes the ecosystem with a marked loss in biodiversity and agricultural productivity leading to a prolonged hiatus whereby a return to the original state may take decades or longer to attain.

The environmental effects accompanying desertification are many and widespread and include such factors as (1) increase in surface albedo (less sunlight is absorbed), (2) decrease of evaporation and transpiration, (3) reduction in the moisture supply to the atmosphere (less water vapor available for condensation), (4) decrease of soil moisture, (5) decrease in precipitation (compounded by increases in albedo and reduced moisture in the atmosphere), which ultimately leads to less favorable conditions for plant growth, and (6) surface temperature changes tend to be highly seasonal and closely related to the hydrologic cycle. On one hand, an increase in surface albedo will result in a decrease of surface net radiation, hence cooling the surface, while on the other hand, a decrease in latent heat as a result of lowered evapotranspiration can lead to the warming of the surface – thus an increase or decrease in surface temperatures will depend largely whether it is the dry or the wet season in the Sahel. Increased dust production from denuded dry soils and dry dune sands as well as from biomass burning (mineral aerosols) can have a number of effects on the environment including influencing the atmospheric radiative transfer directly by scattering and absorbing solar radiation, and indirectly by modifying the optical property and lifetime of clouds. Biomass burning from firewood, charcoal, and animal

dung releases significant amount of greenhouse gases as well as black carbon (soot), which could affect both atmospheric phenomena and human health. Atmosphere-biosphere interactions can also lead to enhancement or a positive feedback loop and become self-perpetuating until a certain threshold is reached. Drought-induced ecosystem degradation will then reinforce the initial anthropogenically driven changes and thus ultimately changing the regional climate, leading to a self-degradation of the land surface as well as persistent drought (Figure 7). Only a return to a decadal or longer above average hydrologic conditions accompanied with changes in land use can jolt (threshold) the system to its former stage.

Synopsis

Drought is more than just a precipitation deficit. It occurs as a result of the complex interplay between natural precipitation deficiencies and the demands of human and environmental water use. It is the most far-reaching climate-related disaster each year, causing hardship to millions of people. Impacts ripple through the economy and may linger for years after the termination of the drought episode. Societal vulnerability to drought is escalating in both developing and developed countries, and at a significant rate. Future climate changes may lead to more frequent and severe droughts.

Introduction

Drought results from a deficiency of precipitation from expected or 'normal.' However, drought is more than just a precipitation deficit. Drought occurs as a result of the complex interplay between natural precipitation deficiencies on varying time and space scales and the demands of human and environmental water use, which may be exacerbated by inefficiencies in water distribution, planning, and management. Drought is a natural feature of the global climate system that occurs in virtually all regions of the world. Drought affects various sectors of society and the natural environment in many ways. It is the most far-reaching climate-related disaster each year, causing hardship to millions of people. According to the National Climatic Data Center, losses from drought in the United States exceeded \$210 billion (United States) during the period 1980–2011. Droughts accounted for roughly 24% of all losses from major weather events (i.e., floods, hurricanes, and severe storms). Droughts and hurricanes are the most costly of natural hazards in the United States. For example, the 2012 drought in the United States affected more than half the country and caused \$30 billion in damages. It was the largest drought, in terms of spatial extent, in the United States since the 1930s. While drought rarely causes fatalities in the developed nations like the United States, it can lead to famine and political instability in other regions of the world. Impacts of drought appear to be increasing in both developing and developed countries, which in many cases is an indication of unsustainable development. Drought is considered to be one of the most complex and least understood of all natural hazards, affecting more people than any other hazard. Numerous definitions of drought exist, reflecting regional variations in climatic characteristics and sector-specific impacts. Simply stated, drought originates from a deficiency of precipitation that results in water shortage for some activity or group.

The Concept of Drought

Drought differs from other natural hazards (such as floods, tropical cyclones, and earthquakes) in several ways. First, drought is a slow-onset, creeping natural hazard. Its effects often accumulate slowly over a considerable period of time and

may linger for years after precipitation returns and the drought ends. Therefore, the onset and end of drought are difficult to identify. This means that scientists and policy makers continue to debate the basis (i.e., the criteria) for declaring an end to a drought. Second, the absence of a precise and universally accepted definition of drought adds to the confusion about whether or not a drought exists and, if it does, its degree of severity. Realistically, definitions of drought must be region-specific and application-specific. This is one reason why there are so many definitions of drought and so many different metrics/indices for measuring it. Third, drought impacts are nonstructural and spread over a larger geographical area than damages that result from other natural hazards. Therefore, quantifying the impacts of drought events and providing disaster relief are far more difficult tasks than they are for other natural hazards. Emergency managers, for example, are more accustomed to dealing with impacts that are structural and localized, responding to these events by restoring communication and transportation channels, providing emergency medical supplies, ensuring safe drinking water, and so forth. These characteristics have hindered our understanding of drought and the development of appropriate strategies to reduce vulnerability and improve response and recovery.

Many people consider drought to be largely a natural or physical event. Figure 1 illustrates that, in reality, drought has both natural and social components. The risk associated with drought for any region is a product of both the region's exposure to the event (i.e., probability of occurrence at various severity levels) and the vulnerability of society to the event. The natural event (i.e., meteorological drought) is a result of the occurrence

Figure 1 Components of drought. National Drought Mitigation Center.

of persistent large-scale disruptions in the global circulation pattern of the atmosphere. Exposure to drought varies spatially and there is little, if anything, that we can do to alter drought occurrence. Vulnerability, on the other hand, is determined by social factors such as population changes, population shifts (regional and rural to urban), demographic characteristics, technology, policy, and social behavior. These factors change over time and thus vulnerability is likely to increase or decrease in response to these changes. Subsequent droughts in the same region will have different effects, even if they are identical in intensity, duration, and spatial characteristics, because societal characteristics will have changed. However, much can be done to lessen societal vulnerability to drought.

Defining Drought

Drought is the consequence of a natural reduction in the amount of precipitation received over an extended period of time, although other climatic factors (such as high temperatures, high winds, and low relative humidity) are often associated with drought and can significantly aggravate its severity. Drought is also related to the timing (principal season of occurrence, delays in the start of the rainy season, occurrence of rains in relation to principal crop growth stages) and the effectiveness of the rains (rainfall intensity, number of rainfall events). Thus, each drought event is unique in its climatic characteristics, spatial extent, and impacts. The area affected by drought is rarely static during the course of an event. As drought emerges and intensifies, its core area shifts and its spatial extent expands and contracts throughout the duration of the event. Because drought affects so many economic and social sectors, numerous definitions have been developed. In addition, because drought occurs with

varying frequency in nearly all regions of the world, all types of economic systems, and developed and developing countries alike, the approaches taken to define it also reflect regional and ideological differences. Impacts also differ spatially and temporally, depending on the societal context of drought. A universal definition of drought is an unrealistic expectation.

There are two main types of drought definitions: *operational* and *conceptual*. Operational definitions are impact- or application-specific that are used in an operational mode by decision makers to identify the beginning, end, and degree of severity of a drought. Conceptual definitions are formulated in general terms and they are used to help explain what a drought is. The large number of conceptual drought definitions that exist illustrates the challenge of accurately describing drought and the lack of agreement in regards to drought definitions. Conceptual definitions of drought are commonly classified into four categories: meteorological, agricultural, hydrological, and socio-economic drought. [Figure 2](#) explains the relationship between these various types of drought and the duration of the event. The impacts associated with drought usually take weeks to months to develop, but this period can vary considerably, depending on the timing of the initiation of the precipitation deficiency.

Meteorological (or climatological) drought is expressed solely on the basis of the degree of dryness (often in comparison to some normal or average amount) and the duration of the dry period. Thus, intensity and duration are the key characteristics of these definitions. Meteorological drought definitions must be considered as region-specific since the atmospheric conditions that result in deficiencies of precipitation are dependent on the climate regime. Most meteorological drought definitions relate actual precipitation departures to average amounts on monthly, seasonal, water year, or annual time scales.

Figure 2 Relationship between types of drought. National Drought Mitigation Center.

Agriculture is usually the first economic sector to be affected by drought because soil moisture supplies are often quickly depleted, especially if the period of moisture deficiency is associated with high temperatures and windy conditions. Agricultural drought links various characteristics of meteorological drought to agricultural impacts, focusing on precipitation shortages, differences between actual and potential evapotranspiration, and soil water deficits. A plant's demand for water is dependent on prevailing weather conditions, biological characteristics of the specific plant, its stage of growth, and the physical and biological properties of the soil. A definition of agricultural drought should account for the variable susceptibility of crops at different stages of crop development. For example, deficient subsoil moisture in an early growth stage will have little impact on final crop yield if topsoil moisture is sufficient to meet early growth requirements. However, if the deficiency of subsoil moisture continues, a substantial yield loss may result.

Hydrological droughts are associated with the effects of prolonged periods of precipitation shortfall on surface or subsurface water supply (i.e., streamflow, reservoir and lake levels, groundwater). Hydrological droughts usually lag the occurrence of meteorological and agricultural droughts. More time elapses before precipitation deficiencies are detected in other components of the hydrological system (e.g., reservoirs, groundwater). Also, water in hydrological storage systems (e.g., reservoirs, rivers) is often used for multiple and competing purposes (power generation, flood control, irrigation, recreation), further complicating the sequence and quantification of impacts. Competition for water in these storage systems escalates during drought, and conflicts among water users increase significantly.

Finally, socioeconomic drought associates the supply and demand of some economic good or service with elements of meteorological, hydrological, and agricultural drought. Socioeconomic drought is associated directly with the supply of some commodity or economic good (e.g., water, hay, hydroelectric power) that is the result of precipitation shortages. Increases in population can substantially alter the demand for these economic goods over time. This concept of drought supports the strong symbiosis that exists between drought and its impacts and human activities. Thus, the incidence of drought could increase because of a change in the frequency of meteorological drought, a change in societal vulnerability to water shortages, or both. For example, poor land-use practices such as overgrazing can decrease animal carrying capacity and increase soil erosion, which exacerbates the impacts of and vulnerability to future droughts.

Operational Definitions of Drought

Developing operational definitions of drought is also challenging because drought has no definitive onset/end, is slow to evolve, and is regionally relative. Operational drought definitions are used to trigger water conservation measures and determine whether (and how much) drought assistance will be provided to affected regions. Failure to adequately define and monitor drought can have a significant negative impact, particularly if it fails to trigger a response (e.g., limiting water use) when one is sorely needed, or if it triggers a response when

one is not required. Operational definitions of drought typically utilize drought indices or metrics like percentage of normal precipitation, Palmer Drought Severity Index, or the Standardized Precipitation Index. However, most drought indices were not specifically designed with this purpose in mind. There is much less discussion about operational drought definitions in the scientific literature, regarding and how they should be developed and used to monitor drought and to trigger drought response. Most of the state drought plans in the United States employ a single set of operational drought definitions for the entire state and these definitions have usually been developed using subjective criteria. It is more appropriate to use objective and standardized approaches to develop operational drought definitions.

Drought Characteristics and Severity

Droughts differ from one another in three essential characteristics: intensity, duration, and spatial coverage. Intensity refers to the degree of the precipitation shortfall and/or the severity of impacts associated with the shortfall. It is generally measured by the departure of some climatic index from normal and is closely linked to duration in the determination of the impact. The simplest index in widespread use is the percentage of normal precipitation, but there are numerous more complex and more effective indices available. It is generally recommended that several indices be used to monitor drought onset and development because each index has its particular strengths and weaknesses. One of the principal difficulties with this (or any) index is the choice of the threshold below which the deficiency of precipitation must fall (e.g., 75% of normal) to define the onset of drought and trigger various mitigation actions or response programs. Thresholds are usually chosen arbitrarily. In reality, they should be linked to the impact. Another distinguishing feature of drought is its duration. Droughts usually require a minimum of weeks to months to become established but then can continue for months or years. The magnitude of drought impacts is closely related to the timing of the onset of the precipitation shortage, its intensity, and the duration of the event. For example, a dry period that begins in the late fall and continues through the winter months in the midwestern United States will likely have negligible impacts. However, if dry conditions persist into the spring and early summer months, agricultural and urban demands for water supplies increase dramatically. Pasture growth will be reduced, affecting livestock producers through supply shortages and increasing prices. Diminished topsoil and subsoil moisture will also affect seed emergence and early growth development of grain crops such as corn and soybeans, eventually affecting yield and crop production, if dry conditions persist throughout the summer months. Urban water supplies are often reduced, forcing water suppliers to impose voluntary or mandatory water conservation measures. As drought conditions extend over more than one growing season, impacts magnify substantially as a result of declining surface and subsurface water supplies and an expanding circle of impacts.

Droughts also differ in terms of their spatial characteristics. The areas affected by severe drought evolve gradually, and regions of maximum intensity shift from season to season. In

Figure 3 Percentage area of the United States in severe and extreme drought, 1895–2013. National Drought Mitigation Center, based on data provided by the National Climatic Data Center, National Oceanic and Atmospheric Administration, US Department of Commerce. <http://www.ncdc.noaa.gov>.

larger countries, such as Brazil, China, India, the United States, or Australia, drought would rarely, if ever, affect the entire country. During the severe drought of the 1930s in the United States, for example, the area affected by severe drought never exceeded 65% of the country (Figure 3). By contrast, drought affected more than 95% of the Great Plains region in 1934. On the other hand, it is indeed rare for drought not to exist in a portion of the United States each year. Thus, the governments of larger countries are more accustomed to dealing with water shortages and have established an infrastructure to respond, albeit reactively. For smaller countries, it is more likely that the entire country might be affected since droughts are usually regional phenomena. From a planning perspective, the spatial characteristics of drought have serious implications. Nations should know the probability that drought may simultaneously affect all or several major crop-producing regions within their borders and develop contingencies for the occurrences of such an event. Likewise, it is important for governments to know the chances of a regional drought simultaneously affecting agricultural productivity in their country as well as adjacent or nearby nations on whom they are dependent for food supplies. In some instances, a nation's primary drought mitigation strategy may be to import food from nearby nations, ignoring the likelihood that a drought may have significant regional impacts on food supplies. Likewise, the occurrence of drought worldwide or in the principal grain-exporting nations, such as occurred during the El-Niño Southern Oscillation (ENSO) event of 1982–83, may significantly alter a developing country's access to food from donor governments.

The Impacts of Drought

The impacts of drought are diverse and often ripple through the economy. Thus, impacts are referred to as direct or indirect. Conceptually speaking, the more removed the impact from the cause, the more complex the link to the cause is. In other words, a loss of yield resulting from drought is a direct or first-order impact of drought. However, the consequences of that impact (e.g., loss of income, farm foreclosures, government relief programs) are secondary or tertiary impacts. Because of the number of affected groups and sectors associated with drought, its spatial extent, and the difficulties connected with quantifying environmental damages and personal hardships, the precise determination of the financial costs of drought is an arduous task. It has been estimated that the average annual impacts of drought in the United States are \$6–8 billion. These figures may be misleading because drought years often occur in clusters, such as the 1930s, 1950s, 1987–89, and 1999–2002 (Figure 3). Impacts during each of these years were much above the annual average. The 1988 drought caused an estimated \$40 billion in damages. The impacts of drought can be classified into three principal areas: economic, environmental, and social. Table 1 presents a simplified illustration of the impacts associated with each of these areas. Economic impacts range from direct losses in the broad agricultural and agriculturally related sectors, including forestry and fishing, to losses in recreation, transportation, banking, and energy sectors. Other economic impacts would include added unemployment and loss of revenue to local, state, and federal government. Environmental losses are the result of damages to plant and animal

Table 1 Classification of drought-related impacts (costs and losses)

<i>Problem sectors</i>	<i>Impacts</i>
Economic	Loss from crop production Annual and perennial crop losses; damage to crop quality Reduced productivity of cropland (wind erosion, etc.) Insect infestation Plant disease Wildlife damage to crops Loss from dairy and livestock production Reduced productivity of range land Forced reduction of foundation stock Closure/limitation of public lands to grazing High cost/unavailability of water for livestock High cost/unavailability of feed for livestock High livestock mortality rates Increased predation Range fires Loss from timber production Forest fires Tree disease Insect infestation Impaired productivity of forest land Loss from fishery production Damage to fish habitat Loss of young fish due to decreased flows Loss of national economic growth, retardation of economic development Income loss for farmers and others directly affected Loss of farmers through bankruptcy Loss to recreational and tourism industry Loss to manufacturers and sellers of recreational equipment Increased energy demand and reduced supply because of drought-related power curtailments Costs to energy industry and consumers associated with substituting more expensive fuels (oil) for hydroelectric power Loss to industries directly dependent on agricultural production (machinery and fertilizer manufacturers, food processors, etc.) Decline in food production/disrupted food supply Increase in food prices Increased importation of food (higher costs) Disruption of water supplies Unemployment from drought-related production declines Strain on financial institutions (foreclosures, greater credit risks, capital shortfalls, etc.) Revenue losses to federal, state, and local governments (from reduced tax base) Deterrence of capital investment, expansion Dislocation of businesses Revenues to water supply firms Revenue shortfalls Windfall profits Loss from impaired navigability of streams, rivers, and canals Cost of water transport or transfer Cost of new or supplemental water resource development
Environmental	Damage to animal species Reduction and degradation of fish and wildlife habitat Lack of feed and drinking water Disease Increased vulnerability to predation (e.g., from species concentration near water) Loss of biodiversity Wind and water erosion of soils Reservoir and lake drawdown Damage to plant species Water quality effects (e.g., salt concentration, increased water temperatures, pH, dissolved oxygen) Air quality effects (dust, pollutants) Visual and landscape quality (dust, vegetative cover, etc.) Increased fire hazard Estuarine impacts; changes in salinity levels, reduced flushing

Table 1 Classification of drought-related impacts (costs and losses)—cont'd

<i>Problem sectors</i>	<i>Impacts</i>
Social	Increased groundwater depletion (mining), land subsidence Loss of wetlands Loss of cultural sites Insect infestation Food shortages (decreased nutritional level, malnutrition, famine) Loss of human life (e.g., food shortages, heat) Public safety from forest and range fires Conflicts among water users, public policy conflicts Increased anxiety Loss of aesthetic values Health-related low flow problems (e.g., diminished sewage flows, increased pollutant concentrations, etc.) Recognition of institutional constraints on water use Inequity in the distribution of drought impacts/relief Decreased quality of life in rural areas Increased poverty Reduced quality of life, changes in lifestyle Social unrest, civil strife Population migration (rural to urban areas) Reevaluation of social values Increased data/information needs, coordination of dissemination activities Loss of confidence in government officials Recreational impacts

National Drought Mitigation Center.

species, wildlife habitat, and air and water quality; damage from forest and range fires; degradation of landscape quality; and soil erosion. Although these losses are difficult to quantify, growing public awareness and concern for environmental quality has forced public officials to focus greater attention on these effects. Social impacts mainly involve public safety, health, conflicts among water users, and inequities in the distribution of impacts and disaster relief programs. As with all natural hazards, the economic impacts of drought are highly variable within and between economic sectors and geographic regions, producing a complex assortment of winners and losers with the occurrence of each disaster. For example, decreases in agricultural production result in enormous negative financial impacts on farmers in drought-affected areas, at times leading to foreclosure. This decreased production also leads to higher prices of grains, vegetables, and fruit. These price increases have a negative impact on all consumers as food prices increase. However, farmers outside the drought-affected area with normal or above-normal production or those with significant grain in storage reap the benefits of these higher prices. Similar examples of winners and losers can be given for other economic sectors as well.

Drought Response and Preparedness

With the occurrence of any natural disaster come appeals for disaster assistance from the affected area. For decades, governments have typically responded to drought by providing emergency, short-term, and long-term assistance to distressed areas. Emergency and short-term assistance programs are often reactive, a kind of 'band-aid' approach to more serious land and water management problems. Actions of this type have long been criticized by scientists and

government officials, as well as by recipients of relief, as inefficient and ineffective. Long-term assistance programs are far fewer in number, but they are proactive. They attempt to lessen a region's vulnerability to drought through improved management and planning. Governmental response to drought includes a wide range of potential actions to deal with the impacts of water shortages on people and various economic sectors. In the United States and other developed countries, agencies of the federal government typically respond by making massive amounts of relief available to the affected areas. Most of this relief is in the form of short-term emergency measures to agricultural producers and few, if any, of these assistance measures in recent years have been aimed at reducing future vulnerability. In developing countries, emergency response is often provided by donor governments, nongovernmental organizations, and international organizations. The assistance that is provided typically is in the form of food aid, health services, access to potable water supplies, and transportation services. Because of the unique character of drought, governments have been less inclined to invest resources to develop well-conceived mitigation programs and contingency plans. This reactive approach to natural disasters is commonly referred to as crisis management. Research has demonstrated that reaction to crisis often results in the implementation of hastily prepared assessment and response procedures that lead to ineffective, poorly coordinated, and untimely response. An alternative approach is to initiate planning between periods of drought, thus developing a more coordinated and proactive response that would more effectively address those persons, areas, and sectors mostly at risk. Also, the limited resources available to government to mitigate the effects of drought could be allocated in a more beneficial manner.

Drought Policy and Planning

Drought planning is defined as actions taken by individual citizens, industry, government, and others in advance of drought for the purpose of mitigating some of the impacts and conflicts associated with its occurrence. Because drought is a normal part of climate variability for virtually all regions, it is important to develop plans to deal with these extended periods of water shortage in a timely, systematic manner as they evolve. This planning process needs to occur at various levels of government and to be integrated between levels of government. The purpose of a drought plan is to reduce the impacts of drought by identifying the principal sectors, groups, or regions mostly at risk and developing mitigation actions and programs that can reduce these risks in advance of future drought events. Generally, drought plans have three basic components: monitoring and early warning; risk and impact assessment; and response and mitigation. Plans will also improve coordination within agencies of government and between levels of government. In the United States, there has been a remarkable growth in the number of states with drought plans. In 1982, only three states had drought plans. By late 2000, 30 states have drought plans and 6 additional states are in various stages of plan development. Today, only three states do have state drought plans in place or under development (Figure 4). Planning methodologies are available to facilitate the planning process (see [Further Reading](#)). This trend demonstrates an increased concern about the potential impacts of extended water shortages and the complexity of those impacts. Drought plans are at the foundation of improved drought management, but only if they emphasize risk assessment and mitigation programs and actions. Many of the drought plans that currently exist in the United States

still emphasize emergency response or crisis management, but in recent years there has been increased focus on state drought plans that are based on mitigation.

Other developed and developing countries are also making substantial progress in drought preparedness through the application of appropriate risk management techniques. Australia developed a national drought policy in the early 1990s and this policy has undergone revision as experience with the policy has increased. The Australian policy is focused on the agricultural sector and seeks to improve the self-reliance or drought-coping capacity of farmers and to promote the sustainable use of natural resources. The government has invested resources in improving longer-range forecasts and other decision support systems to aid farmers in farm management. South Africa also developed a national drought policy that emphasizes the same principles as that implemented by Australia. Many other countries in South America, Europe, Africa, and Asia are following this trend toward improving drought management through the application of the principles of risk management. Before developing a preparedness plan, government officials should first define what they hope to achieve by that plan. Thus, a drought policy statement should be prepared in advance of a plan. The objectives of drought policy should encourage or provide incentives for agricultural producers, municipalities, and other water-dependent sectors or groups to adopt appropriate and efficient management practices that help to alleviate the effects of drought. Past relief measures have usually discouraged the adoption of appropriate management techniques. Assistance should also be provided in an equitable, consistent, and predictable manner to all without regard to economic circumstances, industry, or geographic region. An objective should also seek to protect the natural and agricultural resource base. Degradation of natural resources can result in spiraling economic, environmental, and social costs.

Figure 4 Status of drought planning, United States. National Drought Mitigation Center. <http://drought.unl.edu/>.

Future Droughts

The impacts of future droughts will be determined not only by the frequency and intensity of drought events, but also by the number of people at risk, their degree of risk, and the resiliency of natural systems. As demand for water and other shared natural resources increases as a result of population growth and migration to drought-prone areas, urbanization, environmental degradation, government policies, land use changes, technology and other factors, future droughts can be expected to produce increasingly negative impacts even without any drought frequency or intensity changes. The 2007 Fourth Assessment Report of the Intergovernmental Panel on Climate Change states that “drought-affected areas are projected to increase in extent, with the potential for adverse impacts on multiple sectors, e.g., agriculture, water supply, energy production and health.” In addition, the United States Global Change Research Program assessment states that droughts are likely to become more common and more intense as regional and seasonal precipitation patterns change, and rainfall becomes more concentrated into heavy events.

Therefore, projected changes in climate, population growth, and increased water demands suggest that future droughts will be more severe and have greater impacts than those experienced during the past century.

Summary

Drought is an insidious natural hazard that is a normal part of the climate in virtually all regions. It should not be viewed as only a physical phenomenon. Rather, drought is the result of an interplay between a natural event and the demand placed on water supply by human-use systems. Drought should be considered relative to some long-term average condition of balance between precipitation and evapotranspiration. Many definitions of drought exist; it is unrealistic to expect a universal definition to be derived. The three characteristics that differentiate one drought from another are intensity, duration, and spatial extent. The impacts of drought are diverse and generally classified as economic, social, and environmental. Impacts ripple through the economy and may

linger for years after the termination of the drought episode. Because of the large number of groups and economic sectors affected by drought, the nonstructural nature of its impacts, its spatial extent, and the difficulties in quantifying environmental damages and personal hardships, the precise calculation of the financial costs of drought is difficult. It appears that societal vulnerability to drought is escalating in both developing and developed countries, and at a significant rate. It also appears that future climate changes may lead to more frequent and severe droughts. Therefore, it is imperative that increased emphasis be placed on mitigation, preparedness, and prediction and early warning if society is to reduce the economic and environmental damages associated with drought and its personal hardships.

Flooding

Synopsis

Flooding occurs when water encroaches on normally dry land. Floods can arise directly from atmospheric precipitation or from events that cause precipitation that had fallen earlier to inundate dry land. Flooding is a hazard that occurs worldwide and can have enormous societal impacts. As people encroach on flood-prone regions and urbanization occurs, they become increasingly vulnerable to the dangers of flooding.

Introduction

Flooding is the weather-related hazard that is arguably the most widespread around the globe. It can occur virtually anywhere. A flood is defined as water overflowing onto land which is typically dry. Flooding is often thought of as a result of heavy rainfall, but floods can arise in a number of ways that are not directly related to ongoing weather events. Thus, a complete description of flooding must include processes that may have little or nothing to do with meteorological events. Nevertheless, it is clear that in some ultimate sense, the water involved in flooding has fallen as precipitation at *some* time, perhaps long ago. The origins of flooding, therefore, ultimately lie in atmospheric processes creating precipitation, no matter what specific event causes the flooding.

Floods produce damage through the immense power of moving water and through the deposition of dirt and debris when floodwaters finally recede. People who have not experienced a flood may have little or no appreciation for the dangers of moving water. The energy of that moving water goes up as the square of its speed; when the speed doubles, the energy associated with it increases by a factor of four. Flooding is often coupled to water moving faster than normal, in part because of the weight of an increased amount of water upstream, leading to an increase in the pressure gradient that drives the flow. In most cases, the damage potential of the flood is magnified by the debris the waters carry, which includes trees, vehicles, boulders, buildings, etc. When the water moves fast enough, it can sweep away all before it, leaving behind scenes of terrible destruction (Figure 1).

The effect of the water itself can be devastating on structures and on the objects within them: books, furniture, photographs, electronic equipment, etc. can be damaged simply by being immersed in water, even if they are not directly damaged by the water movement. Moreover, floodwaters typically contain suspended silt, potentially toxic microorganisms, and dissolved chemicals. This means that floods usually compromise drinking water supplies, resulting in short-term shortages of potable water, with the additional long-term costs in restoring drinking water service to the residents of a flooded area. The mud and debris left behind when floodwaters recede can be costly to clean up and represent a health hazard, as well, especially when there are decomposing bodies in the debris. In some situations, floods drive wild animals (including invertebrates of all sorts) from their normal habitats to human

habitations near and within the flooded areas, which can create various problems, especially when those animals are venomous or aggressive.

Although flooding has some large negative impacts on humans, it is also part of the natural processes shaping the Earth. Floodplains along rivers and streams are among the most fertile regions known through deposition of nutrients and relatively high soil moisture content. Most of the so-called cradles of civilization are within floodplains for this very reason (e.g., the Nile River, the Tigris–Euphrates River, among others). Hence, humans have been affected by flooding both positively and negatively since before historical times, whenever they find themselves in the path of these natural events.

Figure 1 Damage resulting from the 1977 Johnstown, Pennsylvania, flash flood event. © The Johnstown Tribune-Democrat, used by permission.

Floods as a Direct Result of Precipitation

When the waters of a flood arise directly from precipitation, atmospheric processes can be identified which are responsible for the event. That is, rainfalls occur that are usually well beyond the average values for the affected area. It is only when those rainfalls exceed the average that land which is usually dry can be affected; that is, a flood occurs. Thus, the rainfall amounts needed for floods cannot be defined in absolute terms. A precipitation event that causes a flood in one location might be well within the bounds of what is typical for another location. Generally speaking, the threshold for flood-producing rainfalls increases as the annual average rainfall for a region increases.

Flash Floods

Flash floods are defined as those flood events where the rise in water is either during or within a few hours of the rainfall that produces the rise. Therefore, flash floods occur within small catchments, where the response time of the drainage basin is short. In part owing to the rapidly rising, fast-moving waters of a flash flood, the damage from them can be devastating (Figure 1). Many hydrological factors have relevance to the occurrence of a flash flood: terrain gradients, soil type, vegetative cover, human habitation, antecedent rainfall, etc. In steep, rocky terrain or within heavily urbanized regions, even a relatively small amount of rainfall can trigger flash flooding. These hydrological factors determine the response of the catchment to the precipitation event. Thus, a flash flood is clearly the result of the concatenation of both meteorological and hydrological circumstances.

Most flash floods associated with rainfall are produced by thunderstorms; that is, deep, moist convection. A single thunderstorm cell is unlikely to produce enough rainfall to cause a flash flood, so the typical flash flood is the result of several thunderstorms moving successively over the same area, known as 'training' thunderstorms (Figure 2), because it resembles the passage of cars in a train. A succession of thunderstorms results when new thunderstorms pass repeatedly over the same place while the overall system of thunderstorms is very nearly stationary. The infamous Johnstown, Pennsylvania flash flood of 19–20 July 1977 was produced by such a system. Thunderstorms forming in northwestern Pennsylvania moved south-eastward, only to be replaced by newly formed thunderstorms, a process that went on for several hours. The result was torrential rainfall concentrated near Johnstown, with amounts exceeding 400 mm. The ensuing flash flood was responsible for 77 fatalities and \$550 million (in 1999 dollars) in damage.

Occasionally, flash floods are created in conditions that are not favorable for thunderstorms but which still produce heavy rainfalls. This can occur when moist air is forced upward over mountains by the wind flow, called *orographic* precipitation. Whenever the air forced upward is very moist, the rainfall can be quite heavy. The steep, rocky terrain also promotes rapid runoff of the rainwater. Flooding along the West Coast of the United States or in the European Alps is often of this type; that is, not involving thunderstorms.

A characteristic of flash floods is the localized nature of the heaviest rainfall. As shown in Figure 3, the most intense

rainfall is typically confined to a relatively small area. When large amounts of this localized precipitation fall within a small drainage basin, flash floods can occur. Sometimes, the location where flash flood damage occurs may actually receive little or no rainfall; that is, the rainfall that causes the problem falls upstream of areas susceptible to damage from the flash flood. This separation between the rainfall and the flood can cause confusion because it may not even be raining in an area for which flash flood warnings are issued. Another factor in the impact of flash floods is that the precipitation causing the event often falls during the night, when it can be difficult to give warnings to sleeping residents. The central part of the United States is well known for its heavy thunderstorm-produced rains during nighttime hours. Worldwide, thunderstorms are most common during the day, but on the central plains of the United States (and in a few other places around the world), the unique geography of the region favors nocturnal thunderstorms. This setting promotes a strong poleward flow of air near the surface from the Gulf of Mexico, called a *low-level jet stream*, during the warm months of the year. Moisture carried by the low-level jet stream helps to maintain thunderstorm systems that often begin during daytime hours on the higher terrain to the east of the Rocky Mountains. Because of the low-level jet stream, such storms can persist well into the nighttime hours, often forming clusters of thunderstorms known as *mesoscale convective systems* (Figure 4).

It is the rapidity of the event that makes flash floods so damaging and dangerous. Flash floods involve rapidly rising, fast-moving waters that can do immense damage; the suddenness of the onset of the flood can result in people being caught unawares and unprepared. Most fatalities result from drowning, with perhaps some traumatic injuries from being carried along in the debris-laden waters and being swept into stationary objects. The potential for loss of human life with flash floods is high. Debris carried in flash floods can form temporary 'debris dams' that typically fail as waters back up behind them. Failure of these debris dams then results in a 'wall of water' surging downstream. Debris dam failure events can happen repeatedly during the course of the flash flood. Not all flash floods are characterized by a 'wall of water' but all of them (by definition) involve rapidly rising floodwaters.

Flash flooding is more likely in cities than in rural areas surrounding a city, because urbanized areas promote runoff of rainfall, rather than permitting most of the rain to be absorbed into the ground. It takes much less rainfall in a city to create a flash flood situation than in a rural area of comparable size.

Flash floods continue to be a major contributor to loss of life, in spite of improved precipitation forecasting. Some noteworthy examples include events in the Big Thompson Canyon in Colorado (1976 – 144 fatalities) and near the town of Biescas in the Spanish Pyrenees (1996 – 86 fatalities).

Tropical cyclones often create devastating flash floods as a result of torrential rainfalls. In late October of 1998, Hurricane Mitch caused more than 9000 fatalities (the exact number is not known), mostly in Nicaragua and Honduras, in Central America, from flash floods and landslides associated with its rainfall. It was the worst weather disaster in terms of

Figure 2 Schematic of the 'training' effect. (a) At this time, there are four numbered thunderstorm cells in various stages of development. Cell I is mature, with both updrafts and downdrafts, and heavy rain is about to commence at point 'X.' Cells II, III, and IV are still developing, and have only updrafts. Cell II has precipitation forming aloft. The hatched contours are radar reflectivity, in units of dBz, which is related to the rainfall rate. (b) About 15 min later, Cell I's updraft is dissipated, and it is now dominated by downdraft. Heavy rain continues at 'X' while Cell II is maturing and developing a downdraft. Cells III, IV, and now V are still immature. (c) About 15 more minutes have elapsed. Cell I's rainfall is continuing but it is now nearly dissipated, while Cell II is entering late maturity. It is still raining at 'X' but now the rainfall is from Cell II, and heavy rain from Cell II is descending from aloft. Now Cell III is developing its first precipitation aloft. Cells IV and V are still immature. Adapted from Figure 7 in Doswell, C.A. III, Brooks, H.E., Maddox, R.A., 1996. Flash flood forecasting: an ingredients-based methodology. *Weather Forecasting* 11, 560–581.

casualties in the Western Hemisphere during the twentieth century.

River Floods

River floods, in contrast to flash floods, typically unfold over days, or even months. This is because they occur in large basins involving 'main stem' rivers like the Missouri, or the Nile and are usually the result of many individual rainfall episodes spread out over many days. In fact, within a river flood event, numerous localized flash flood events can occur. Again, hydrological factors often contribute to a river flood, but river floods are not so sensitive to them as are flash floods. River floods are usually the result of a stagnant synoptic-scale weather pattern, whereas individual thunderstorm systems can cause flash floods. Localized heavy rainfall events occur many times during a period of days or even months, each contributing its share of rainfall to the tributaries, which then discharge into the main stem of a river. Saturated soils from repeated heavy rainfall promote runoff. The river rises gradually in response to all the input rainfall. The river flood potential of a situation can be increased by concurrent snow-melt and other factors besides rainfall.

The major flooding event during June and July of 1993 was the result of a weather pattern (Figure 5(a)) that produced a storm track across the upper Midwestern United States. Abnormally low heights of the pressure surfaces (associated with cool temperatures) over the Northern Plains produced a pattern in which traveling weather disturbances intensified in the Midwest after crossing the Rocky Mountains. This pattern aloft also produced an anomalously strong poleward flow of low-level moisture from the Gulf of Mexico into the Midwest. Mesoscale convective systems developed almost every evening during the early summer, typically persisting through the night. These passed repeatedly over the nearly the same areas, resulting in widespread significant rainfalls (Figure 5(b)) for the period over the Lower Missouri and Upper Mississippi basins. In addition to these factors, considerable rainfall had fallen over the region during the previous several months, providing a hydrological setting that favored runoff of the precipitation. This event produced disastrous flooding that persisted for many weeks.

Owing to the long timescale of the rising waters, river floods pose a lower risk of fatalities; people have more time to take proper actions. Of course, some casualties result from waiting

Figure 4 False-color enhanced infrared satellite image of a mesoscale convective system, with the light red colors indicating the coldest (therefore the highest) clouds. Note that this image is at 0345, local time, which corresponds to 0845 UTC. Adapted from NOAA image.

until it has become too late to respond to the threat. Levee and dam failures, as well as intentional rapid release of impounded waters to prevent the catastrophic failure of the flood-control structures, can produce rapidly rising water situations embedded within a river flood, and these also can contribute to loss of life.

Because of the large scale of river floods, the damage figures may be enormous; easily into billions of dollars. Crop losses are a major factor in the costs of river floods, whenever large tracts of prime agricultural land along floodplains are inundated. Levees are often used to protect populated areas, so the failure of those levees can generate major property losses. The damage and dislocations along the Upper Mississippi and Lower Missouri basins during the summer floods of 1993, during which several levees were breached, illustrate the huge impact such events can have.

Floods Arising from Nonprecipitation Events

Apart from floods resulting directly from rainfall, there are many ways that precipitation can cause floods, perhaps long after it has fallen. When flowing water is impounded by the construction of dams, there is some risk that the dams will fail. For example, Johnstown, Pennsylvania was inundated by a dam failure during a rainfall event in 1889. Such rapid releases of stored water can be cataclysmic, manifesting themselves as an enormous 'wall of water' choked with debris.

Floods also can arise through the melting of snowfall. In situations where the preceding winter's snowpack is deep, a sudden change to warm temperatures in the spring can result

in abnormally rapid melting and runoff of the snowmelt. The devastating flood created in Grand Forks, North Dakota in April of 1997, is an example. Occasionally, warm rain falls directly onto the melting snow, exacerbating such situations by speeding the melting process and adding more liquid water.

Deposits of snow and ice on volcanic peaks can melt rapidly during eruptions. The resulting runoff, often turned into a thick slurry by the inclusion of volcanic ash, roars down the mountainside and is called a *lahar*. A tragic example occurred with the Nevado del Ruiz volcano in Colombia on 13 November 1985, which killed more than 23 000 people, mostly in the town of Armero. Another occurred in Iceland in 1996 on the Vatnajökull glacier, with no fatalities owing to its remote location. Lahars can continue occasionally for years after an eruption, when heavy rains fall onto ash deposited by the volcano.

During the winter and late spring, ice can build up on rivers in cold climates. The breakup of the ice can create *ice dams* on the river. These ice dams cause the waters to back up, sometimes flooding the land upstream of the ice dam. Then, the breakup of the ice dam can result in a flash flood wave that surges downstream of the ice dam's position.

Other flood situations can develop along the shores of the world's oceans and even with large freshwater lakes. *Tsunamis*, such as the tragic event on 26 December 2004 caused by a major earthquake in the Indian Ocean near Indonesia, which also can be initiated by landslides (both above and below the water), flood coastal areas with multiple surges of water that can penetrate deep inland in flat coastal zones. The effects of tsunamis can be experienced far from their source, as

Figure 5 (a) Map of the 700-hPa heights (thin lines, in dam) and height anomalies (shading, in m) for June/July 1993, and (b) observed precipitation for the same period (shading, in mm). Based on data supplied by Janowiak, J., of the NOAA Climate Prediction Center.

illustrated in Figure 6. Storms of all sorts, including tropical cyclones, can drive the waters before the winds into *storm surges* that inundate coastal zones when the storms are near the land. Large lakes, such as the Great Lakes in the North

Central United States can experience flooding due to *seiches*, which are surges of water (usually wavelike) within enclosed bodies of water. Seiches can be caused by earthquakes or by atmospheric processes.

Societal Impacts and Their Mitigation

The results of floods on society worldwide are substantial. Flooding is responsible for many drowning fatalities in tropical cyclones, either from storm surges or from freshwater rain-induced flash floods. Flash floods and river floods typically produce more fatalities on the average than either tornadoes or hurricanes in the United States. In many parts of the world, flood fatalities are associated with the most significant weather-related disasters. Flood damage cost in the United States is now on the order of several billion dollars annually and the numbers continue to rise.

Many people live and play in flood-prone areas; for example, within floodplains of rivers and their tributaries, as well as along coastlines that are vulnerable to storm-caused flooding from tsunamis, tropical cyclones, and nontropical storms. Development of flood-prone areas for habitation and recreation has been increasing, with a corresponding increase in the risks to life and property. In 1993 and again in 2011, Mississippi River floods provided a grim reminder of the risks of building permanent structures within floodplains, even when flood-control measures have been taken.

In the case of flash floods, it is difficult to take measures to protect property, owing to the rapidity with which the event happens. However, prevention of flash flood casualties is possible, provided warnings can be issued and acted upon properly in a timely fashion. Considerable attention has been paid to increasing public awareness of the dangers of driving into rapidly rising floodwaters, for instance, as a result of recent experiences with flash floods. Unfortunately, situations can still arise where warnings are not issued in time. People living and engaging in recreational activities in places prone to flash floods need to be alert during heavy rainfalls and be

prepared to seek safety even when they do not receive timely warnings.

For river floods and other relatively slow-developing situations (such as rising snowmelt or ice action events), it may be possible to reduce the property damage as well by removing the contents of structures. Obviously, any structures (and their contents) built in flood-prone areas are permanently at risk; the only way to guarantee them not being affected by floods is to move them out of those areas. Prevention of fatalities in river flood events is a matter of heeding the warnings of danger and getting residents out of the danger areas before the number of options is reduced by the rising waters and by the breaching of levees or other flood-prevention structures.

Forecasting the details of flooding events is an important part of mitigation. Knowing precisely when and where a flood will occur would no doubt be helpful, but it is also important to be able to anticipate the magnitude of the flood. An example of this is the tragedy of the 1997 Grand Forks, North Dakota case, where the river level was only a few feet higher than that forecast. Those few feet, however, had a large impact, because the flood-control operations were based on the lower forecast value. When the river rose above that level, the flood-control measures failed catastrophically. In reality, such a forecast can never be a precise statement; uncertainty is implicitly a part of every forecast, a point that deserves greater emphasis in the future.

Flooding, by its very nature, is usually a result of both meteorological and hydrologic processes; the character of a flood is determined both by the detailed behavior of the precipitation and by the nature of situation in which the event is likely to occur (soil conditions, amount of antecedent rainfall, etc.). It is not likely that precisely detailed forecasts of flooding events will ever be possible, although it certainly is

well within our capability to anticipate the *possibility* of most flood events. The challenge for reducing the social impacts of floods is how best to make use of the *uncertain* meteorological and hydrological forecasts that are within practical means. The requirement is to make effective use of whatever forecasting capability we have, even as we seek to improve that capability.

Effects of Human Activities on Flooding

In addition to the risks to lives and property that people take by moving into flood-prone areas, development for human use often involves clearing land of its native vegetation and altering the characteristics of the ground cover. Vegetation works together with the soil to store rainfall, so when that vegetation is cleared, rainfall runoff can increase substantially. Rather than being absorbed by the soil and its natural vegetation, in areas where that vegetation has been cleared (either for construction or for agriculture), heavy rainfall is more likely to run off and pour into streams and rivers, increasing the potential threat from flash floods and river floods. Construction of roads and buildings also acts to increase runoff, replacing soil with impervious materials. Such construction increases dramatically the fraction of the rainfall that runs off, regardless of antecedent rainfall. Human-caused fires also can produce at least temporary increases in the runoff potential in the headwater regions of streams and rivers. It is evident that human activities are increasing the potential for floods around the world.

Again recalling the Mississippi River floods of 1993 as an example, the issue of flood control through levees and other structures was dramatically recalled to public attention. The value of structural methods for flood control (levees, flood-control dams, breakwaters, etc.) remains controversial, but the 1993 floods made it apparent that structures such as levees *can* be breached during *major* flooding episodes, even though they may be able to contain lesser events. Structural failures create rapidly rising waters (flash floods) artificially within a river flood event, increasing the hazards to human life as well as destroying property. The decision about when and where to take structural approaches will continue to be a challenge.

Finally, the use of flood-prone areas for human activities puts lives and property at risk, although the major flood events may be separated by many years. The relatively long time between events can lead to complacency and subsequent

disasters. The choices associated with land use are a continuing challenge, now and in the future. When humans live and play in ways that put them in the path of potential floodwaters, major societal impacts are inevitable.

Synopsis

Groundwater and surface water are two important components of the hydrologic system. One objective of hydrologic studies is to understand the spatial and temporal variations of water storage and movement. This article first presents an overview of the global distribution of water, the hydrologic cycle, and the water balance concept. It then describes the physical principles governing the movement of groundwater and surface water by focusing on the hydraulic gradient as the driving force for flow: Darcy's law for groundwater and Manning's equation for streams. Finally, applied aspects of hydrology are discussed as they relate to water contamination, land subsidence, hydrothermal fluids, and hydroseismicity.

Introduction

Water is one of the most precious and indispensable natural resources. As important components of the hydrologic system on Earth, groundwater and surface water impact numerous aspects of Earth processes and many facets of daily life. Water at the Earth's surface directly interacts with the atmosphere, and water in the subsurface continuously redistributes geothermal energy and dissolved minerals in the Earth's crust at a variety of temporal and spatial scales. Hydrology encompasses the study of the occurrence and movement of water both at the land surface and in the subsurface. Although the term groundwater usually refers to the water that occurs beneath the water table in saturated soils and rocks, study of soil moisture movement in the unsaturated zone above the water table is well within the realm of groundwater studies.

Focusing on the physical dynamics of groundwater and surface water, this article first presents a brief overview of water as a resource. The discussion is then devoted to the main concepts and governing principles applied to physical processes controlling the movement of groundwater and surface water. Finally, the applied aspects of hydrology as they relate to water contamination, land subsidence, and geological processes are briefly reviewed.

Water as a Resource

The presence of abundant liquid water makes the Earth a unique planet in the solar system. This abundance has been challenged throughout human history as numerous local and regional conflicts over water resources have erupted. Evidence of early attempts to harness water for human purpose has been documented by archaeologists. For example, clever water usage for irrigation can be traced as far back as 4500 years ago in the Middle East. A remarkable water-collecting tunnel system dating from around 500 BC in Egypt has been unearthed. As world population grows, the local demand for water is expected to grow, particularly in arid developing countries. Shown in [Figure 1](#) are the historical and anticipated

global water extractions from 1900 to 2025 and how water use is partitioned among agricultural, domestic, and industrial uses. Increasing trends are observed in all three sectors and in the total extraction (bar graphs in [Figure 1](#)). The partitioning of water (pie charts in [Figure 1](#)) indicates an increased share in domestic use from 14% in 1900 to forecasted 24% in 2025 but a decreased share in agricultural use from 80% in 1900 to forecasted 60% in 2025. The increased domestic share and the decreased agricultural share may suggest food shortage problems in the future if crop production water use efficiency cannot keep up with global population growth and increased demand for food. Total freshwater withdrawal in the United States from 1950 to 2005 also followed a generally increasing trend ([Figure 2](#)). The decrease in the 1980s was primarily due to increased irrigation efficiency and reduction in water consumption by the thermoelectric power industry as a result of improved power plant technologies and efficiencies. The continual increase in domestic water use has compensated for the decrease in industrial water use.

Global Water Distribution

[Figure 3](#) shows the water distribution in the Earth system. Of all water on the Earth, 97.33% of it is stored in the ocean and is too salty to be directly used for human consumption. Ice caps and glaciers, the next largest water reservoir, hold 2.12% of the global water and account for 79% of the total freshwater. Groundwater in the upper 800 m of the subsurface holds 0.31% of the water on the Earth. Only the portion in the upper few hundred meters of the Earth's crust is economically accessible and fresh enough for human consumption. The salinity of groundwater increases with depth and often becomes too high to be useful as a resource below 1 or 2 km. Surface waters including lakes and streams hold 0.158% of the global water, and they have served as the main water resource for people, primarily owing to their easy accessibility. The water in the atmosphere, 0.083% of total water, is much more than that occurring in all of the streams (0.003%) plus all soil moisture (0.002%) in the world.

Figure 1 Global water extractions from 1900 to 2025 (bar charts) and the partition of water by different sectors (pie charts). Reproduced from UNEP, 2008. *Vital Water Graphics – An Overview of the State of the World's Fresh and Marine Waters*, 2nd edn. Nairobi, Kenya: UNEP, ISBN: 92-807-2236-0.

Hydrologic Cycle

Powered by solar energy, the hydrologic cycle is the endless movement of water from one part to another part in the Earth system (Figure 4). Water evaporates into the atmosphere from bare land surfaces and from open waters such as oceans and lakes. Plants also lose water to the atmosphere through transpiration. Evaporation and transpiration are collectively known as evapotranspiration. Ice and snow can lose water through sublimation, the process of changing solid water into vapor without first melting to liquid. Water falls back to the Earth's surface as precipitation in the form of snow and rain. Upon reaching the surface, water flows overland as runoff to streams or infiltrates into the subsurface. Some of that infiltrated water becomes recharge to the groundwater system. Groundwater moves

through geologic media, discharging to springs and surface waters. Much of the migrating groundwater and surface waters eventually make their way to the oceans. The rates of water flow in the hydrologic cycle vary spatially and temporally. Streamflow is relatively rapid, with residence times of days to months. This is in contrast to the residence time of groundwater, the time it remains in the subsurface since recharge, which varies from months in sediments at shallow depths to tens of thousands of years in rocks several kilometers deep in the Earth's crust.

Water Budget Balance

One of the primary objectives in studying groundwater and surface water is to understand the spatial and temporal variations of water storage and movement. The basic principle

Figure 2 Freshwater withdrawals in the United States from 1950 to 2005. Reproduced from Kenny, J.F., Barber, N.L., Hutson, S.S., Linsey, K.S., Lovelace, J.K., Maupin, M.A., 2009. *Estimated Use of Water in the United States in 2005*. U.S. Geological Survey Circular 1344.

governing these variations is conservation of mass or water balance. This principle requires that the amount of water entering a control volume during a specified time period minus the amount of water exiting equals the change in storage in that volume. The principle of a water balance is often applied over a watershed, also referred to as a drainage basin, which is a geographic region where all the water flows to a common destination or an outlet. Watershed delineation is primarily based on topography where topographic divides, or ridges, form the boundaries of a watershed. Smaller watersheds or subbasins can be nested within a larger watershed. It should be noted that groundwater can flow across the boundaries of watersheds, under the topographic divides of the basin. Considering steady-state flows averaged over a long period of time, the water balance equation is:

$$P + Q_{in} + G_{in} = ET + Q_{out} + G_{out} \quad [1]$$

where P is the precipitation, Q_{in} and Q_{out} are stream inflow and outflow, respectively, G_{in} and G_{out} are groundwater inflow and outflow, respectively, and ET includes evaporation and transpiration. All quantities have the dimension ($L \, t^{-1}$).

It is a common misconception that the amount of groundwater that can be safely extracted from the subsurface at steady state is equal to some fraction of preextraction groundwater recharge to that system. However, as suggested by the water balance shown in eqn [1], any extraction of groundwater, adding to the right side of the equation, must be balanced by increased inflows on the left side or decreased outflows on the right side of eqn [1]. In general, any extraction of groundwater during development will reduce natural groundwater discharge to springs and surface waters over the long term, which may be undesirable to people and harmful to the environment.

Physical Hydrological Processes

Surface Water Dynamics

Streams, lakes, and wetlands are the surface waters of primary interest in hydrologic studies. The following discussion focuses on streams. A stream is a body of water flowing down slope along a more or less confined course. A river is a stream with a significant amount of flow. A stream with no tributaries is designated as a first-order stream, the confluence of two first-order streams is the beginning of a second-order stream; the confluence of two second-order streams is the beginning of a third-order stream, and this pattern can continue to form higher-order streams. The branching patterns of stream orders have been studied using a fractal approach that provides a mathematical framework for treatment of similar geometric characteristics over a range of scales. Streams play vital geologic roles in incising valleys, transporting dissolved load and sediments to the sea, and reshaping the landscape over time. Stream processes are affected by a variety of factors such as the steepness of the stream, the cross-sectional area of the stream, water velocity, and sediment load. The dimensionless Reynolds

Figure 4 The hydrologic cycle: Water evaporates from open waters at the Earth's surface and transpires from vegetated lands. Upon reaching the land surface, precipitation infiltrates the soil to replenish groundwater as recharge or is removed by evapotranspiration. The remainder flows overland as runoff to open waters. Groundwater flows through the subsurface and returns to surface waters and oceans. The water table is the boundary between the unsaturated zone above and the saturated zone below. This particular diagram is most representative of humid regions where the water table is near the ground surface and streams and lakes are surface manifestations of the water table.

number, (Re), is a convenient parameter describing the state of flow as laminar or turbulent. It is defined as $(Re) = \rho vY/\mu$, where ρ is the density of water ($M L^{-3}$), v is the average flow velocity ($L t^{-1}$), Y is the average flow depth (L), and μ is the dynamic viscosity of water ($M L^{-1} t^{-1}$). In streams, laminar flow occurs when (Re) is less than 500. Turbulent flow occurs when (Re) is greater than 2000 and circulating eddies form in turbulent regions. Transitional flow lies between laminar and turbulent flow regimes. Actual streamflow is seldom laminar, but when the degree of turbulence is small flow is often considered to be in the laminar range. The Manning equation is one of the most commonly used equations for computing the average flow velocity in a stream channel:

$$v = n^{-1} R^{\frac{2}{3}} S^{\frac{1}{2}} \quad [2]$$

where n is the Manning roughness coefficient, R is the hydraulic radius (L) defined as the ratio of the flow channel's cross-sectional area to its perimeter, and S is the channel slope.

Water Table

In near-surface sediments and soils, water is in the form of moisture in the unsaturated zone where void spaces are partially filled with water. At depth, void spaces are completely filled with water, which forms the saturated zone. The boundary between the unsaturated and the saturated zone marks the water table (Figure 4), although a transitional tension-saturated region called the capillary fringe occurs at the interface. The configuration of the water table in humid regions is generally a subdued replica of the topography, near the surface in low lands but deeper at high elevations. The depth of the water table varies in both space and time. In humid regions, the water table can be at or near the surface and streams and lakes are surface expressions of the water table. In drier semiarid and arid regions, the water table can be hundreds of meters below the land surface. Under natural conditions, the water table can rise in wet seasons as excess precipitation percolates through the unsaturated zone to the water table and drop in dry seasons when water is lost through evaporation and transpiration. The most reliable way to locate the water table is to drill wells. Because lateral groundwater flow follows the slope of the water table, knowledge of the water table configuration gives useful basic information about the direction of groundwater flow.

Porosity, Permeability, and Hydraulic Conductivity

The primary factors controlling groundwater occurrence and movement in the subsurface are the hydraulic properties of the geologic material and the hydrologic driving force. The most important material properties are porosity and permeability. Porosity, defined as the percentage of pore space in a unit volume, may vary from 0–5% for tight igneous and metamorphic rocks to 25–50% for sands or fractured rocks. Clay can have a porosity as high as 90%, but few of the pores are interconnected. Porosity is a measure of geologic materials' capacity for storing water. A related quantity is known as specific yield, which is used to describe the volume of water that is partially drained by gravity from a porous material as the water table declines.

Permeability is a measure of geologic materials' ability to transmit water and reflects how well pores are interconnected. In the simplest case, it is defined as follows: $k = Cd^2$, where k is the permeability (L^2), C is a proportionality constant related to grain size, sediment sorting, and packing arrangement, and d is the particle diameter for which 10% of the grains by weight are finer (L). Depending on the type of fluid flowing through a system, the ease of flow differs. One can imagine that a fluid that is sticky like honey would flow much slower than would clean water in the same medium under the same conditions. Therefore, it is necessary to consider not only the medium but also the fluid properties. The hydraulic conductivity is introduced and is defined as: $K = k\rho g/\mu$, where K is the hydraulic conductivity ($L t^{-1}$), ρ is the fluid density ($M L^{-3}$), g is the gravitational acceleration ($L t^{-2}$), and μ is the dynamic viscosity of the fluid ($M L^{-1} t^{-1}$). Values of hydraulic conductivity vary over many orders of magnitude from $10^{-13} m s^{-1}$ for tight rocks to over $1 m s^{-1}$ for sands and gravels.

The most reliable means of obtaining hydraulic conductivity values are field-scale pumping tests using sets of observation wells. When water is withdrawn from or injected into a well, the rate of water level decline and recovery in the well and in adjacent observation wells can be measured by a pressure transducer and recorded by a data logger. The rate of water level decline during pumping, and recovery after pumping is stopped, is used to compute the hydraulic conductivity of the material in the vicinity of the pumping and observation wells. Large-scale tests with many observation wells are more reliable than single well tests, known as slug tests. This is largely because local material properties near the slug test well are not necessarily representative of the regional hydraulic conditions. Laboratory tests on core samples are commonly conducted to obtain hydraulic conductivity values, but they are typically valid at the centimeter scale and not necessarily representative of larger scales because hydraulic properties typically vary over small distances in natural groundwater systems. Computer modeling is also commonly employed as an indirect means of inferring hydraulic conductivity at different scales based on changes in groundwater levels due to regional addition or removal of groundwater over time and space.

Aquifers and Aquitards

Aquifer and aquitard are terms used to characterize hydrogeologic systems. A geologic unit that is highly permeable and can store and transmit a significant amount of groundwater is called an aquifer. When an aquifer is bounded by the water table on the top, the aquifer is called an unconfined aquifer. When an aquifer is confined between two much less permeable units, it is called a confined aquifer. Water pressure in confined aquifers is usually higher than pressure in unconfined aquifers. Thus, when a well is drilled into a confined aquifer, the water level in the well will rise to above the top of the aquifer, and may even rise above the ground surface, which creates artesian flow. An aquitard, also known as a confining bed, is a much less permeable geologic unit. Because no naturally occurring porous material is completely impermeable, aquifers and aquitards are identified to distinguish their relative degree of high and low permeability, respectively. In general, gravel,

sandy materials, limestone, or highly fractured rocks make good aquifers, whereas clay-rich, poorly sorted sediments, and unfractured rocks often form aquitards. The term aquiclude has been used for describing an impermeable unit, but this term has become obsolete.

Water in an Unsaturated Zone

Near the land surface at shallow depths, soils and sediments are often partially saturated, which creates a region known as an unsaturated or vadose zone. Saturation is defined as the fraction of pores that contain water, and it varies from 0 to 1, representing dry and fully saturated conditions, respectively. The water in an unsaturated zone clings onto solid particle surfaces and is sustained by capillary forces. Pore pressures in the unsaturated zone are conventionally expressed as negative values, reflecting the use of atmospheric pressure as the zero reference pressure. The pore pressure distribution and the rate of moisture movement vary spatially, depending on soil type, and temporally in response to short- and long-term climate conditions.

Infiltration is an important process in the unsaturated zone, which involves downward movement of moisture under wet conditions. The infiltration rate over a small area can be measured using a ring infiltrometer. A commonly used type of infiltrometer consists of two rings with a smaller inner ring nested inside a larger outer ring. The infiltrometer can be pushed several centimeters into the subsurface and both rings filled with water. The rate of water seepage into the ground from inside the inner ring is used to estimate the infiltration rate. The diameter of the rings of a portable infiltrometer varies from a few centimeters to 1 or 1.5 m. It is important to note that not all infiltrated water makes its way to the water table as recharge because some is temporarily stored in the near-surface sediments and subject to evapotranspiration.

In contrast to infiltration, evaporation and transpiration draw moisture upward. Evaporation not only causes water loss from surface waters, such as lakes and rivers, but also from near-surface soils and sediments. Water evaporates as a vapor diffusion process that is largely controlled by the energy exchange between radiation, or sensible heat from the atmosphere or ground, and the heat energy change in the evaporating body. A direct method to determine the evaporation rate is known as the pan evaporation approach. It involves exposing a cylindrical pan of water to the atmosphere in clearings where precipitation also can be monitored. The standard U.S. National Weather Service Class-A pan is 1.22 m in diameter and 25.4 cm deep. Transpiration is a process where water is lost to the atmosphere through the vascular systems of plants. The transpiration process works by absorption of water by plant roots, translocation of liquid through plant vascular systems, and transpiration into the atmosphere through stomata or openings in leaf surfaces. Although transpiration is considered a diffusion process, water is first pulled through the plant by a potential energy gradient, before diffusing into the air in response to a vapor pressure difference. There are a variety of methods to estimate transpiration. One is based on direct measurement using a lysimeter, a tank of soil, water, and plants in which the water loss due to transpiration can be assessed.

Another general approach is based on a surface energy balance that relies on a set of measurements to compute the latent heat flux, which is proportional to transpiration.

Groundwater in a Saturated Zone

Below the water table, the movement of groundwater occurs as slow-moving seepage through the pore spaces in sediments and rocks or as relatively fast flow through rock fractures and dissolution channels. Groundwater velocities are generally much slower than streamflow rates, and may be as low as 1 mm day^{-1} . Under natural conditions, a groundwater velocity on the order of centimeters per day would be considered typical and 1 m day^{-1} or more would be considered high. The low velocity of groundwater has important implications for geological processes like metamorphisms and ore formation as well as contaminant movement because it leads to long residence times. The extent of groundwater flow systems varies from local meter-scale hill slopes to multikilometer-scale regional basins. Groundwater velocities are typically faster in shallow, local flow regimes and slower in deeper, regional flow systems. As a result, the residence time of groundwater varies significantly, ranging from days in shallow, small systems to tens of thousands of years when considering deep flow in large sedimentary basins. Quantitative descriptions of groundwater flow require a depiction of the hydraulic head field and application of Darcy's law, which are discussed in the following subsections.

Hydraulic Head

Hydraulic head is one of the key variables in describing a groundwater system. It represents the mechanical energy per unit weight of fluid in the system. Hydraulic head, h , is defined as: $h = h_p + h_z$, where h_p is the pressure head and h_z is the elevation head. All three quantities have the dimension (L). The pressure head represents the energy due to pore fluid pressure, and the elevation head represents the gravitational potential energy arising from elevation. Because groundwater velocities are so slow, kinetic energy is typically negligible. Water flows from high to low hydraulic heads along a hydraulic gradient (discussed presently). *In situ* measurement of hydraulic head is accomplished by measuring the water level elevations in wells. First, the depth to groundwater is measured with the aid of a manual tape, electric sounding instrument, pressure transducer, or similar devices. Next, water level elevations are obtained by subtracting the measured depth to water from the land surface elevation. In regions where spatial hydraulic head differences are slight, typically in areas of gentle topography, water level measurements require accuracies of millimeters.

Darcy's Law

The basic equation governing groundwater movement is Darcy's law. In 1856, Henry Darcy, a French engineer in Dijon, France, performed an experiment involving water flow through a cylindrical sand column. The experimental data led to an empirical relationship between water flow and the experiment setup parameters. This relationship later became well-known as

Darcy's law in groundwater studies. Darcy's law is a simple gradient-flux relation and is as common in groundwater studies as analogous laws are in other fields such as Fick's law describing solute flux, Ohm's law describing electrical current, and Fourier's law describing heat conduction. In a one-dimensional system, Darcy's law is expressed as:

$$Q = -K \frac{dh}{dx} A \quad [3]$$

where Q is the volumetric flow rate ($L^3 t^{-1}$), K is the hydraulic conductivity ($L t^{-1}$), h is the hydraulic head (L), x is the coordinate (L), A is the cross-sectional area of flow (L^2), and dh/dx is the hydraulic gradient. It is clear from eqn [3] that the hydraulic gradient is the primary driving force for groundwater flow. The negative sign in the equation denotes that groundwater flow is in the direction of decreasing hydraulic head, down the hydraulic gradient. In describing groundwater flow, groundwater velocity, V_{gw} , is commonly computed. It is defined by the following equation:

$$V_{gw} = \frac{Q}{(A)(n_{eff})} = \frac{K}{n_{eff}} \frac{dh}{dx} \quad [4]$$

where n_{eff} is the effective porosity, or pore space through which water flows unimpeded by stagnant, dead end zones. V_{gw} is the average rate of a parcel of water occupying a volume of many pores and grains.

It should be noted that groundwater flow can be driven by other spatial differences in potentials besides a hydraulic gradient. For example, groundwater flow also can be driven by gradients in temperature, solute concentration, or both. In the absence of these other gradients, Darcy's law is a simple and sound formula to compute groundwater flow.

Wells

The primary need for wells is to withdraw water from the subsurface. Wells also serve as a window to the subsurface in the study of groundwater. Some wells are used for monitoring hydraulic heads (water levels) and also for sampling water for chemical analyses. When a well is pumped, a cone of depression forms around the well as the water level declines; the drawdown in the depression cone is greatest near the pumping well and less severe with distance from the well. The rate of water level decline is typically quite different depending on whether the pumping occurs in a confined or in an unconfined aquifer. Under the same pumping rate in different aquifers consisting of similar geologic materials, initially, a larger water level decline is expected in a confined aquifer and a smaller decline in an unconfined aquifer. For similar declines due to pumping, the volume of water obtained from confined aquifer storage is much less than that obtained from unconfined aquifer storage. When pumping from a confined aquifer, the porous material is not drained and does not desaturate. Rather, water comes from storage by compaction of the aquifer material accompanying slight rearrangement of grains plus expansion of water when pore pressure is reduced due to pumping. When pumping from an unconfined aquifer, water comes from storage by partial draining of saturated pores as the upper portion of the aquifer is converted into an unsaturated zone.

Surface Water and Groundwater Interaction

Groundwater interacts with lakes, streams, and wetlands across the landscapes from mountains to plains to shores of bays and oceans. In managing water resources, conjunctive use of surface water and groundwater has increasingly become a common practice, particularly in arid and semiarid regions. The basic concept of conjunctive use is to utilize surface water while storing excess water in aquifers under wet climate conditions when streamflow is high, and to withdraw water from the aquifers under drier conditions when demand is high but streamflow is low. The success of a conjunctive use project depends heavily on the dynamics of the interaction between the surface water and the groundwater. Streams can either gain water from or lose water to aquifers. Many streams do both in different reaches of the stream and at different times in the same reach. The rate and direction of flow in or out of the stream can also vary as the elevation of the water table relative to the stream surface fluctuates. Pumping of groundwater near streams can decrease the quantity of flow feeding a stream as baseflow, and even change a gaining stream into a losing stream. Moreover, interactions between groundwater and surface water affect water quality. When the groundwater in shallow aquifers is contaminated (for example, from agricultural practices of applying fertilizer and pesticides), the shallow aquifers can contaminate surface water as the groundwater flows toward a stream. The opposite can occur when a stream is heavily contaminated (for example, from mine waste drainage in mountainous regions). Mixing of groundwater and surface water affects other natural environments such as wetlands and aquatic environments when acidity, temperature, nutrients, and dissolved oxygen are altered by mixing. Streams, lakes, and wetlands may become acidic as they receive atmospheric deposition of chemicals, such as sulfate and nitrate. Acidic precipitation directly affects the well-being of aquatic ecosystems. In some cases, significant groundwater flow into a stream may help neutralize and reduce the stream acidity to tolerable levels for aquatic organisms.

Applied Aspects of Hydrology

The scientific aim of hydrology is to seek understanding of the mechanisms of water movement in the Earth system and the roles that water plays in natural processes. The applied aspect of hydrology, on the other hand, relates to using scientific knowledge to guide safe and sustainable use of water resources, investigating the impact and consequences of improper water use, and evaluating means to protect water resources. Although only two areas are discussed below, applied hydrology contributes to society and the environment far beyond what is included in these subsections.

Water Contamination

Water contamination has increasingly become a concern in modern times. Application of pesticides and fertilizer is common agricultural practice and has resulted in aerial contamination of water as excess irrigation water percolates through soils and carries the chemicals into groundwater and

directly or indirectly into surface waters. Contamination sources that occur over large areas are known as nonpoint sources; sources confined to small areas are called point sources. Multiple closely spaced point sources can form a nonpoint source. Landfills are major point sources of water contamination. Aging and leaking liners around landfills allow leachate, a mixture of water and dissolved chemical, to leak into groundwater. Wastes from mines, industrial disposal, nuclear reactor and weapon facilities, petroleum spills, and leaking underground storage tanks have all contributed to the contamination of groundwater and surface waters. Understanding contaminant transport is important for predicting future behavior of contaminated waters and designing effective remediation procedures.

Three major mechanisms control the transport of contaminants in water: advection, spreading, and chemical reactions resulting in retardation, decay, or degradation. Advection is the process of transporting contaminants by moving water and is often the dominant mechanism once the contaminants make their way into highly permeable aquifers. Spreading involves diffusing, dispersing, and mixing of the dissolved contaminants with clean waters. Spreading is due in part to a suite of mixing processes and dispersal mechanisms accompanying solute migration along relative preferential flow paths at multiple spatial scales. Spreading, mixing, and attenuation also occur due to the slow movement of solutes into and out of relatively stagnant zones, such as dead end pores and local immobile regions of low permeability. Advection and spreading are the physical processes of contaminant transport, while retardation, degradation, and decay result from chemical reactions occurring as the contaminated water migrates through and interacts with geologic media. Retardation, degradation, and decay are simple terms used here to express a collection of many complex chemical and biological processes. Chemical reactions can slow down the rate of migration of contaminants and even degrade or sequester certain compounds. These reactions may include sorption, precipitation, oxidation, reduction, ion exchange, and biological activity.

Land Subsidence

Extraction of groundwater plays a direct role in land subsidence. Uneven subsidence of the historic Tower of Pisa in Italy has created a tourist attraction. Subsidence has been a problem in many cities and towns as building foundations and road surfaces become cracked and tilted as the ground subsides. When a large amount of water is withdrawn from the subsurface, void spaces in rocks, and sediments collapse, which leads to compaction and subsidence. The Santa Clara Valley and nearby San Joaquin Valley in Northern California have experienced regional subsidence of several meters due to excessive groundwater pumping in order to sustain productive agriculture and water use in rapidly urbanizing areas. As Las Vegas Valley in Nevada has turned into a fast-growing metropolitan area, groundwater is being rapidly depleted and this area has also suffered problems with land subsidence and ground fissures due to horizontal movement. Subsidence may also occur from drainage of soils that are rich in organic carbon as microbial decomposition converts organic carbon to

carbon dioxide gas and water. Subsidence at the rate of 20–80 mm year⁻¹ has been observed as a result of the decomposition of the remains of shallow water sedges and reeds in California's Sacramento–San Joaquin Delta and in Florida's Everglades. More catastrophic subsidence takes place with the formation of sinkholes associated with localized collapse of subsurface cavities. Often triggered by a decline in the groundwater level, sinkholes typically form in areas underlain by carbonates (e.g., limestone and dolomites) and evaporites consisting of easily dissolved minerals such as salt, gypsum, and anhydrite.

Role of Groundwater in Geologic Processes

Water exists in pore spaces in sediments and rocks to a depth of more than 10 km. The degree of pore water decreases with depth in response to a general decrease of porosity with depth. Groundwater plays an essential role in mineral dissolution and precipitation, and impacts metamorphic processes by altering rocks' mineral compositions over geologic time. As water flows through deep sections of the crust or passes through thermally active regions, such as in the vicinity of a cooling magma, the heated waters become hydrothermal. Hot springs emerge at the locations of hydrothermal water discharge. Groundwater carries dissolved minerals and transports them to ore-forming locations. Petroleum forms, as natural gas or crude oil, at significant depths of burial of marine organism and sediments. Groundwater then transports the petroleum to shallower locations, a process known as secondary migration in petroleum system studies.

The mechanical interaction between groundwater and rock deformation has been thought to contribute to triggering earthquakes. As pore pressures in faults and the surrounding area increase, faults become lubricated and weakened, setting the stage for an earthquake. The best-known example is the documented earthquakes between 1962 and 1972 in the Denver area when liquid waste was injected underground into fractured granites a few kilometers deep at the Rocky Mountain Arsenal. The time and frequency of the earthquakes were correlated strongly with the time and volumetric rate of waste injection. Interest in fluid-induced seismicity is on the rise as fluid injection activities associated with carbon dioxide sequestration in geologic formations and hydrothermal exploration are expected to intensify in coming years.

Synopsis

This article describes the general approach for hydrologic modeling and prediction. After the hydrologic system is conceptualized, mathematical model can be set up and numerical model can be developed. Then data such as precipitation, land use–land cover, digital elevation, and soil texture need to be prepared for the hydrologic simulation. Before the model can be used for the prediction, it needs to be calibrated for assessing how well the simulation can reproduce the observed hydrologic variables.

Introduction

Hydrologic models have become an indispensable tool to study hydrologic processes and the impact of natural variability and anthropogenic factors on the hydrologic system. Mathematical models, which are governed by the laws for conservations of mass and momentum, are used to describe the temporal and spatial variation on various physical processes in the hydrologic system along with information concerning climate, land use–land cover, and hydrology. Modeling the hydrologic response to various natural and human-induced changes has the potential to contribute to the understanding of these physical processes such as flow and solute transport in the surface and subsurface and the atmosphere–land surface interaction.

Two types of hydrologic models have been used in most applications: lumped conceptual models and physically based models. A lumped model is generally applied in a single point or a region for the simulation of various hydrologic processes. The parameters used in the lumped model represent spatially averaged characteristics in a hydrologic system and are often unable to be directly compared with field measurements. In general, lumped models use simple bookkeeping procedures to quantify physical processes by simulating the temporal variation of various physical processes in a hydrologic system. The advantage of these models over physically based models is that the conceptual parameterization in the models is simple and computation is efficient. With the availability of spatially distributed digital and remotely sensed data sets such as precipitation, elevation, vegetation, etc., many distributed lumped models have been developed in recent years. These kinds of models have been widely used in climate, meteorological, and hydrologic studies to simulate hydrologic processes.

Many physically based distributed-parameter models have been developed to facilitate various hydrologic and climatic applications over recent years, especially for simulating spatiotemporal variation in hydrologic processes under climate changes such as global warming. These models represent hydrologic processes in a physically rigorous manner because they use process-based partial differential equations (PDEs) to describe the spatial variability of hydrologic processes over time. Within this framework provided by these equations, it is possible to estimate governing parameters through field studies. One disadvantage of such models is that the representation of physical processes in these models is often too

crude and the scales of measurement for many hydrologic parameters are incompatible with the scales used in the models. Studies indicated that the uniform effective parameters (e.g., saturated hydraulic conductivity) cannot represent the ensemble heterogeneity, resulting in a significant underestimation of hydrologic variables (e.g., streamflow). These physically based distributed models can be referred to as conceptual lumped models in some sense. The physically based models are more complex and require more computing time for solving PDEs numerically and considerable effort to master all their intricacies, such as model calibration. For simulating the hydrologic response (e.g., soil moisture content, groundwater level) to climate forcing (e.g., storms and human-induced global warming), these models currently offer no advantage over the traditional conceptual lumped water-balance models.

Physically based hydrologic models are an important evolutionary step in representing hydrologic processes and spatially distributed data. At the present time, the ability to represent spatially varying processes is outstripping our ability to collect various data sets. The need for the research on the better representation of physical processes in space and time is evident given the increasing availability of digital products (e.g., distributions of elevation, soil, vegetation) and remotely sensed data (e.g., soil moisture, vegetation), along with new remote sensing technologies for measuring temporal and spatial variability in precipitation.

Research on data assimilation and analysis, subgrid-scale variability in precipitation and hydraulic parameters, subgrid-scale model calibration, prediction uncertainty analysis, and inclusion of fine-resolution surface and subsurface hydrology in various hydrologic and climatic models are being conducted in various research institutes to facilitate an interactive link between the hydrosphere and the atmosphere. Simulation and prediction of various physical processes in the hydrologic system are among the principal areas of study in the current fields of hydrology and climate.

General Approach of Hydrologic Modeling

Climate variability has substantial impact on hydrologic, biologic, and ecologic systems such as water availability and quality, floods, and droughts. Such climate variability has been intensified due to the human-induced climate changes and

Figure 1 Frame structure of coupled climate and hydrology models. Source: Yu, Z., Pollard, D., and Cheng, L., 2006. On continental-scale hydrologic simulations with a coupled hydrologic model. *Journal of Hydrology* 331, 110–124.

results in many extreme flood and drought events in recent years. The effects of climate variability on economic vitality and the quality of life (e.g., 1988 North American drought and 1993 Mississippi flood in the USA) indicate that future climate change will be of considerable global, national, and regional importance. The current emphasis on the climate impact analysis and hydrologic modeling requires improved specifications of the interactions between the atmosphere and the hydrosphere. The difficulty in reconciling the discordant scales in climate change and hydrologic research hampers the understanding of how regional hydrologic systems respond to climate forcing. Part of the difficulty can be attributed to

insufficient progress on the theoretical side, related to deficiencies in our abilities to couple atmospheric and hydrologic processes that occur over spatial scales ranging from microscopic to global (specifically ranging from 10^{-4} to 10^6 m) and over time scales ranging from 10^{-4} to 10^7 s. Various parameterization schemes have been used to reconcile the discordant scales of hydrologic and atmospheric models. The approach involves numerical modeling to bridge the gap in scale between global circulation models (GCMs) and hydrologic models by embedding a regional climate model within a GCM so that the natural variability at the regional scale can be represented within the system (Figure 1).

The nested climate models used for studying the effect of climate change on the hydrologic system indicate that changes in the hydrologic system induced by a climatic change could lead to a further change in climate, ecosystems, agriculture, and hydrology. Many comprehensive hydrologic models such as the Biosphere–Atmosphere Transfer Scheme have been developed to integrate hydrology into the climate system by coupling the physical processes from different systems. Such an integrated hydrologic model system, including components from soil hydrology, surface water hydrology, and groundwater hydrology, is necessary to understand how perturbed climate conditions can modify regional hydrologic systems and, in turn, how the modified hydrologic conditions can modify the climatic system.

Traditionally most hydrologic models have been developed to simulate individual hydrologic processes such as rainfall–runoff partitioning, soil moisture flow, overland flow, and groundwater flow while some comprehensive models are used to simulate all the processes within the hydrologic cycle. In general, any use of hydrologic models for hydrologic and climate studies follows five main steps (Figure 2). After the purpose of hydrologic modeling is well-defined, the conceptual model then can be constructed to describe the hydrologic system and its components that need to be simulated. In the second step, the various mathematical models with various PDEs can be used to describe individual processes within the hydrologic system and computer codes in various computer languages (e.g., C, Fortran) can be developed to solve these PDEs in the mathematical models. In general, the numerical solution of these PDEs must be verified by comparing to known or analytic solutions. The second step can also be completed by selecting existed computer codes that have been verified in previous applications (e.g., MODFLOW). The third step, data preparation, is to compile and analyze available

meteorological and hydrologic data for the hydrologic simulation. Additional data can be obtained through laboratory and field works, if necessary. After all required data being integrated into the models, the models should be calibrated to available field-observed data (i.e., streamflow, groundwater level). So the calibrated models can then be used to predict the hydrologic response to various external forcings (e.g., future water usage, land use–land cover change, and climate change).

System Conceptualization, Mathematical Model Setup, and Model Development

There are many surface and subsurface hydrologic processes in the hydrologic system (Figure 1). Many conceptual and mathematical models have been developed to describe these physical processes in time and space and various numerical schemes (i.e., finite-difference and finite-element methods) are available to solve various PDEs for the simulation of hydrologic processes. The following sections describe some of the major flow processes such as soil water flow, overland flow, and groundwater flow while other processes such as sediment and contaminant transport will not be described here.

When the precipitation reaches the ground, it partitions into components of surface runoff and infiltration. After the water enters the soil column, the soil water flow in the unsaturated zone can be described by the following form of Richards' equation:

$$-\frac{\partial q(z, t)}{\partial z} = \frac{\partial}{\partial z} \left[K(z, t) \frac{\partial \psi(z, t)}{\partial \theta} \frac{\partial \theta(z, t)}{\partial z} \right] + \frac{\partial K(z, t)}{\partial \theta} \frac{\partial \theta(z, t)}{\partial z} \quad (1)$$

where q is the vertical moisture flux, θ is the volumetric water content, z is depth, t is time, K is the unsaturated hydraulic conductivity, and ψ is the hydraulic potential. The Richards' equation can be numerically solved using the Crank–Nicholson numerical scheme and a finite-difference scheme of forward in time and backward in space or other numerical methods. Various schemes are available for relating K and ψ to the volumetric water content because K at a given time is a function of constant saturated hydraulic conductivity and soil moisture status. Infiltration and evaporation can be treated as either a source or a sink, respectively, in Richards' equation or the upper boundary condition of the soil profile. The calculation of evaporation on the bare soil and evapotranspiration on the vegetation canopy can be completed with various methods (e.g., the Penman–Monteith method).

The overland flow will form soon after the rainfall–runoff partitioning and can be formulated as a kinematic wave with a flow-direction algorithm to account for the overland flow delay and storage in each grid cell. Mathematically, one-dimensional overland flow may be described as

$$\frac{\partial d}{\partial t} + \frac{\partial q}{\partial x} = i_e, \quad q = \alpha d^m \quad (2)$$

where $d = d_{(x,t)}$ is the depth of overland flow, $q = q_{(x,t)}$ is the rate of overland flow, i_e is the excess rainfall rate, α is conveyance, and m is surface roughness. The overland flow is discretized into a large number of smaller segments to solve the kinematic-wave flow and the equation can be solved numerically for

Figure 2 Flow chart of hydrologic model application.

the one-dimensional flow. In general, a conservative numerical scheme is implemented in the model to maintain the numerical stability in some extreme cases.

The overland flow quickly reaches nearby streams to form channel flow. The channel flow can be simulated hydraulically and hydrologically. The Muskingum–Cunge method or other channel routing schemes can be used for channel-flow routing through the channel networks that are derived from digital elevation models (DEMs). For instance, the extended finite-difference form of the governing equation can be written in the Muskingum channel routing method:

$$K \frac{d}{dt} [\varepsilon Q_x + (1 - \varepsilon) Q_{x+1}] = Q_x - Q_{x+1} \quad (3)$$

where Q_x is the inflow to a given stream reach, Q_{x+1} is the outflow from a given stream reach, K is a travel time parameter, and ε is a weighting factor. The routing equations are produced using a finite-difference form of the above equation. The outflow of a stream reach is calculated at each time step and routed to downstream reach along DEM-derived channel networks, eventually to the basin outlet.

The following second-order PDE is used to describe groundwater flow in an aquifer:

$$\frac{\partial}{\partial x} \left(T \frac{\partial h}{\partial x} \right) + \frac{\partial}{\partial y} \left(T \frac{\partial h}{\partial y} \right) = S \frac{\partial h}{\partial t} + Q_{\text{net}} \quad (4)$$

where T is transmissivity, h is hydraulic head, S is storativity, t is time, and Q_{net} is net groundwater withdrawal rate. Q_{net} includes groundwater recharge from infiltration, evaporation of shallow groundwater, withdrawal of groundwater from wells, and other sources or sinks, such as induced infiltration of groundwater from the stream network.

In general, the simulation domain for a basin is discretized into a set of rectangular cells with dimensions Δz , Δx , and Δy . Δz is the vertical thickness of the aquifer, and Δx and Δy are the cell dimensions in the x - and y -coordinate directions (Figure 2). A finite-difference or finite-element scheme can be used to discretize the hydrologic system for the numerical solution of the flow domain. Many iterative methods such as the method in MODFLOW (developed by U.S. Geological Survey (USGS)) are available for obtaining solutions for the above PDE.

The interaction between a stream system and groundwater can be simulated with Darcy's law. The calculated inflow/outflow is a function of the hydraulic head difference between the groundwater and the river stage at a given stream reach. When the groundwater level is lower than the streambed, water flows from the stream to the groundwater. When the groundwater level is lower than the streambed, the stream will dry out and eventually there will be no channel groundwater interaction.

After the implementation of numerical schemes for solving various PDEs in the hydrologic system, the developed codes for hydrologic models need to be tested against to known and analytic solutions before they can be used for modeling applications. For the specific applications, the simulation domain must be set up with defined boundary conditions. So the given forcings (i.e., meteorological data and water usage) can be used to drive the simulation of various hydrologic processes.

Data Compilation and Preparation for Hydrologic Modeling

Data compilation and preparation is a major fundamental part of hydrologic modeling. The work involves compiling various available field and digital data sets and processing and integrating these data sets into models for hydrologic simulations. Sources of data can be from various government agencies and institutes. With the availability of new technology, ground-based and remotely sensed data sets as well as the collected data through traditional field methods have been used for hydrologic modeling. Some data are required to be reprojected or reformatted for the specific models.

For topography-based hydrologic models, DEMs are routinely used to describe the land surface topography that contains crucial information for the surface water flow and the interaction of surface water and groundwater. After DEMs are conditioned for removing spurious sinks and peaks, DEMs can be used to determine the flow direction of surface water at a grid cell by comparing the elevation at a grid cell to elevations of neighboring grid cells within the simulation domain assuming that the water always flows from high level to low level. With DEMs, a flow accumulation data set can be obtained in which the contributing area that drains to a grid cell is determined for each grid cell. The DEMs and derived data sets of flow direction and flow accumulation can then be processed to delineate drainage and stream networks, overland flow paths, watershed and subwatershed boundaries, and other features. Derived stream networks facilitate the channel–shallow groundwater interaction while the derived overland flow paths provide accurate prediction of the rainfall–runoff partitioning and soil moisture status over overland flow paths.

Simulations of various hydrologic processes require spatially distributed information on land use–land cover, soil type, and hydraulic properties besides the topography. Many digital soil data sets are available from various sources. For instance, the Natural Resources Conservation Service, U.S. Department of Agriculture, compiled the State Soil Geographic (STATSGO) soils data. In general, these digital data sets are stored in a Geographical Information System format. The hydraulic parameters (i.e., the average saturated hydraulic conductivity and the average capillary suction) data sets can be derived by assigning a value for each grid cell based on various parameterization schemes of hydraulic variables and the soil texture from STATSGO soil data. Then, these derived data sets of various hydraulic parameters can be integrated into models for the hydrologic simulation.

With the development of remote sensing and satellite technology, these data sets hold great potential for practical application to regional ecology, hydrology, and planning. The satellite data can be used to derive a variety of surface parameters, such as radiant surface temperature and vegetation fraction; these variables can be used for both spatial and temporal comparisons and for regional hydrologic modeling of important hydrologic processes. The remotely sensed data such as vegetation classification can be obtained from the AVHRR and Landsat TM images. Spatial distributed data of meteorological variables (e.g., precipitation, temperature, wind speed) are available from NEXRAD, radar, and satellite images at a time resolution from minutes to days. With the improved

Figure 3 Procedure of model calibration. Source: Freeze, R.A., and Cherry, J.A., 1979. Groundwater. Prentice-Hall, pp. 604.

resolution on these data sets, the more accurate simulation of various hydrologic processes is expected in both temporal and spatial scales.

Different types of field-observed data are available for the hydrologic simulation and model calibration that will be discussed in the next section. There are networks of rain gages over the world. At outlets of many river systems, gage stations are available to measure daily streamflow rates and other hydrologic variables. Groundwater levels are also available from many wells and many other data such as evapotranspiration and moisture content are obtainable from local specific regions. For instance, USGS provides infrastructure for monitoring stations and collecting measured data of streamflow and groundwater level while the National Oceanic and Atmospheric Administration maintains the collection of meteorological data.

Model Calibration

Complexity in the hydrologic modeling over large space and long times has prompted a significant need for model calibration or parameter optimization. Model calibration is a demonstration that the model is capable of reproducing field-observed values of various hydrologic variables (e.g., streamflow, soil moisture, and well-observed groundwater level) (Figure 3). Prediction of various hydrologic variables based on an uncalibrated flow model are sterile and undefensible. Generally, the goodness-of-fit between simulated and measured variables is not satisfactory based on the initial values of hydrologic and hydraulic parameters used in the model. The goodness-of-fit can be improved by the adjustment or optimization of these parameter values until the difference between simulated and measured variables is satisfactory during this model practice. The adjustment process most commonly is based on trial-and-error changes in a parameter while other parameter values are held constant. Some

numerical models are now equipped with a semi-automated or automated procedure to optimize one or multiple parameters. The range of adjustment to values of hydrologic and hydraulic parameters must be constrained by plausible site-specific field data such as streamflow, water levels, hydraulic conductivity, and so on. The difficulty in achieving a good calibration is that boundary conditions and values of hydrologic and hydraulic parameters are always known with uncertainty.

Goodness-of-fit calibration can be evaluated through visual comparison and statistical measures. Visual comparison includes scatterplot of simulated versus measured variables, simulated and field-based temporal and spatial distribution, and spatial distribution of residuals. Statistical measures consist of mean error, absolute mean error, and root mean-squared error, between simulated and observed variables.

The trial-and-error calibration involves with manually adjusting parameters to match the simulated results (e.g., streamflow and groundwater level hydrographs) with field-observed historical records. The fitness between the simulation and observation can be evaluated visually and statistically after each simulation with changed parameters. Knowledgeable modelers are able to conduct acceptable model calibration with this approach. On the other hand, the calibration process could be a very frustrating and time-consuming practice for many untrained modelers and sometimes even for experienced modelers when many parameters are changed simultaneously. The disadvantage for such approach is the low efficiency and the lack of standard measures in evaluating the performance of model calibration.

While the trial-and-error calibration is still the most common method for calibrating models of all kinds, many automatic or semi-automatic direct or indirect techniques are available to solve an inverse problem in various hydrologic systems. Automatic direct or indirect model calibrations require setting up objective functions, developing optimization algorithms, setting up termination criteria, and of course,

using observed data or derived variables as calibration targets. The direct approaches use an inverse operator to solve the problems directly, while the indirect approaches use an iterative scheme. For the indirect approaches, various sampling procedure schemes (e.g., Monte Carlo and Latin Hypercube samplings) are available to sample data that cover the range of adjustable variables systematically. In effect, the simulation problem is solved many times over with the coverage of the potential solution space. Ultimately, the process finds the optimum solution, providing a set of parameters that yield the best fit between the observed data and simulated results.

For any model calibration, objective functions need to be set up for variables (e.g., streamflow, groundwater level) that will be optimized during the calibration process. The least-squares method, a common method in the model calibration, is equivalent to the minimization of the sum of squares of the residuals (also called objective function or fitness measure). The general form for a steady state is given by

$$\text{Obj} = \sum_{i=1}^n w_i [s_i^o - s_i^c]^2 \quad (5)$$

where w_i is a weighted factor, s_i^o is the observed data, s_i^c is a simulated result, i is the index for location points, and n is the number of location points.

The weighted factor represents the percentage of importance allocated to a variable at particular locations. If the sum of all weighted factors is 1.0, the above equation becomes the simple least-squares function. It is feasible to zone spatially for both steady state and transient state, although execution times will increase significantly, especially for the transient state, as the degrees of freedom in parameter values increase. The objective function can be constructed for hydrologic variables that can be used as calibration targets (e.g., streamflow and groundwater level). Objective functions, based on a weighted least-square error criterion, can then be used to drive the calibration process. Different combinations of various changes in different optimizing parameters are selected for each simulation run. The objective is to minimize the difference between measured data and simulated results. The objective function for a transient simulation can also be formed as

$$\text{Obj} = \sum_{j=1}^m \sum_{i=1}^n w_{i,j} [s_{i,j}^o - s_{i,j}^c]^2 \quad (6)$$

where m is the number of time steps, j is the index for time steps, and other variables are as defined previously. The transient calibration requires much more computational time than the steady-state calibration due to the additional time dimension. There are other alternatives to the least-squares method such as the maximum-likelihood approach for objective functions.

The direct approaches use an inverse operator to solve the problems directly. Let h^o be the observed hydrologic variables and h^c be the simulated hydrologic variables. Then, according to Taylor's series expansion, the equation can be written as

$$\sum_{j=1}^m \frac{\partial h_i^c}{\partial p_j} \delta p_j = h_i^o(p + \delta p) - h_i^c(p) \quad i = 1, \dots, n \quad (7)$$

In a matrix form, the above equation is written as

$$\mathbf{J} \delta \mathbf{p} = \mathbf{r} \quad (8)$$

where $\mathbf{J}$ is a rectangular Jacobian matrix, $\mathbf{p}$ is the parameter vector to be inverted, $\delta \mathbf{p}$ is the parameter correction vector, and $\mathbf{r}$ is the residual vector between the measured and simulated hydraulic heads. In order to solve the above equation, the transpose of matrix $\mathbf{J}$ multiplies both sides of the equation. The result is a system of equations with m unknowns. A problem occurs because the solution of matrix system is unstable. Marquardt's approach, which involves adding terms to the diagonals of the matrix $\mathbf{J}^T \mathbf{J}$, can overcome this problem. The Levenberg-Marquardt method or Marquardt method (iterative procedures) can be used to solve this system.

After the model calibration, the sensitivity analysis is needed to investigate the uncertainty in the calibrated model caused by the uncertainty in the estimation of various parameters. The sensitivity analysis can be conducted by evaluating the hydrologic flow system in response to various parameter disturbances based on the calibrated hydraulic parameters. The analysis involves perturbing the values of the hydraulic parameters with respect to the best estimates and examining how the simulated hydrologic variables change. The common approach is to evaluate one parameter at a time; all other parameters are kept constant while a given parameter is being evaluated. Then various parameters are varied simultaneously to examine the behavior of the hydrologic flow system under different situations. By doing this, the nonuniqueness of solution of the parameter estimations for the hydrologic flow system can be evaluated and other issues along with the model uncertainty can be assessed.

Model Prediction

With the set of optimized hydraulic parameters from the model calibration, the calibrated model can be used to conduct predictive simulations. The predictive simulations can be driven by external forcings (e.g., climate change scenarios) to derive the system response to future events. Some climate and hydrology problems require the hydrologic modeling to predict the system response for as many as thousands of years. For instance, the risk assessment of contaminant transport for storing low-level nuclear wastes in arid regions requires predicting the water flow in the unsaturated and saturated zones for a time scale of 10 000 years.

How good predictions are depends on how well the model is calibrated assumed mathematical and numerical models are properly established and how creditable future external forcings are, which are used to drive predictive simulations. Because of the nonlinearity of natural hydrologic systems and simplified model structures or assumptions as compared to the actual complex natural physical processes, the calibration process cannot guarantee that the global minimum can be found and so the calibrated model could produce unrealistic results beyond the confident period. In general, the calibrated model should not be used to predict the system in the future longer than twice the period of model calibration with available field-observed

data. In some cases, due to the lack of available long-period historical data for model calibration and the nature of some applications that require an extended period prediction, there will be always uncertainty in predictive simulations. So users must conduct a detailed assessment of the uncertainty on any future prediction of system response as well as the uncertainty associated with model calibration and future external forcings.

The hydrologic cycle plays an important role in the climate system. The two-way interaction between the hydrologic and climate is a crucial element in our current and future hydrology and climate modeling to understand how perturbed climate conditions can modify regional hydrologic systems and, in turn, how the modified hydrologic conditions can influence the climatic system. Data assimilation and analysis of remotely sensed and satellite-derived information should be integrated into hydrologic models to better represent subgrid-scale spatial and temporal variability in meteorological and hydrologic parameters. The model calibration and subgrid-scale model simulation of various hydrologic components. In addition, prediction of uncertainty analysis and inclusion of fine-resolution surface and subsurface hydrology are some important topics in such an interactive link.

Palmer Drought Severity Index

L Nkemdirim, University of Calgary, Calgary, AB, Canada

Synopsis

Drought damages the physical environment, which could compromise the socioeconomic well-being of affected communities. The degree of damage and compromise typically depends on the severity of the event. Wayne Palmer (1965) designed and calibrated an index that is widely used to measure drought severity (Palmer Drought Severity Index – PDSI) both in the present and the past. It is also utilized in a forecast mode. The index is based on the difference between the amount of water required to support the existing water requirement at a place and time and the actual water available at that place and time. Droughts occur when the difference is negative, while wet conditions prevail when positive. The Index of drought (wetness) is determined from a cumulative plot of that difference over monthly time steps. Palmer's model is a two-part system. The first part is the Hydrological Index, which thoroughly accounts for the exchange of water between the atmosphere and the ground. The second part is a meteorological modification that times the onset and end of a drought (wet) event.

Introduction

The Palmer drought severity index (PDSI) is widely used to classify and manage droughts and wet periods. Details of its development and rationale are provided in this article. Some of the criticisms directed at the Index are discussed briefly in the Section [Criticism of the Palmer Index](#). However, this text is not a critical review of PDSI. The objective is to help a potential user decide its adequacy for a specific application. Droughts are the main focus, but wet events, which are scaled by the Index, are treated when relevant.

Drought: Definition, Significance, and Cause

The general sense of a drought is a prolonged absence of sufficient precipitation during a period when it is normally expected. Some disciplines have particular outcome-dependent definitions. Meteorologists defined droughts by the time interval between large precipitation events. In agriculture, drought is said to occur if the supply of moisture from precipitation or soil storage is inadequate for optimum crop growth. A long rainless period may not be so classified if crop yield is unaffected. When streamflow is adequate for established uses under a given water management system, a significant precipitation-free period may not be considered a drought by the water engineer. However, if the duration of precipitation deficiency over a large geographical area is months rather than weeks, and precipitation amounts are well below normal, the senses of drought conveyed by various discipline-specific definitions converge.

Droughts degrade the physical environment. They dry out soils, damage vegetation, and reduce streamflow. Impacts on socioeconomic health can be far reaching. They include threats to food security, industrial production, and population stability. Drought-driven environmental refugees are found in every continent. The African Sahel has been particularly vulnerable to mass migration due to persistent droughts. In Canada and the United States, the droughts of the 1930s significantly restructured the socioeconomic landscape in the West and Midwest.

Droughts are caused by anomalies in atmospheric circulation, which produce air subsidence over a stricken area. They may be intensified and/or prolonged by land surface processes

and the energy–water balance they drive. An index tuned to capture this combination of atmospheric and land surface forcing could approach general applicability.

Drought Index

A drought index is a numerical scale used to describe the severity of a dry (wet) period. There are many drought indices in current usage, many of them discipline specific. [Palmer \(1965\)](#) distinguished himself by constructing one that

- is conceptually simple for qualitative interpretation;
- crosses disciplinary boundaries with sufficient flexibility to recommend its use, in modified form if necessary, in many sectors;
- allows comparison of severity to be made over both time and space;
- ensures that values assigned to severity reflect variations in both duration and intensity such that impacts of long-lasting but mild events can be distinguished from those caused by short but very intense ones;
- contains a mechanism for determining the onset and end of an event;
- enables differentiation between aridity and drought and between drought and a naturally occurring dry season;
- is calculable from easily obtainable data; and
- possesses a forecast potential.

Drought Parameters

A drought (wet period) is normally described by three parameters, namely, duration, magnitude, and severity. In order to isolate and relate these parameters, a truncation level Y_0 is established to separate drought from wet events ([Figure 1](#)). Y_0 may be constant, as in [Figure 1](#), or may vary through time and space to reflect different water requirement thresholds. The function $Y_{(t)}$, which quantifies relative dryness (wetness) at time t , can be construed as a drought index. Index values with $Y_{(t)} < Y_0$ represent drought, while those with $Y_{(t)} > Y_0$ indicate wet conditions. Duration is the time span between successive crossings of the Y_0 line by Y_t (e.g., $t_2 - t_1$). Magnitude is the mean deviation of moisture conditions at $Y_{(t)}$

Figure 1 Conceptual model of a drought index.

from Y_0 over duration $t_2 - t_1$, and severity is the cumulative deviation of those conditions over the duration. The dimension of t_j (the averaging period) should be small enough to provide enough samples for meaningful statistical analysis but sufficiently long so that events are statistically independent of one another. Additionally, the duration Δt_i must not trivialize the incidence of an event. Each of the two broad index categories, namely, $Y_t < Y_0$ and $Y_t > Y_0$, may be subdivided into classes to reflect increasing severity of dryness or wetness, and decisions must be made on the location of subdivision boundaries that are physically meaningful. Figure 1 shows severity division for droughts.

Palmer Drought Severity Index

The main features of the PDSI are listed in Section [Drought Index](#). The present section explains how they were achieved. At a later stage, a distinction is made between Palmer's hydrological index and his meteorological index. Until that point is reached, the term 'PDSI' is utilized in a generic sense.

Drought as Defined by Palmer

Palmer defined a drought as a significant reduction of available moisture below that required for the near-normal operation of the established economy of a region. The qualification 'established economy' is important because it differentiates a drought from normal states of aridity such as deserts and semiarid regions as well as dry seasons. The specification of 'region' underscores spatial variations in water culture, which permits different degrees of dryness for drought to exist in different areas. For established economies, Palmer chose croppable land areas in the US Midwest.

PDSI is a meteorological concept grounded in detailed hydrological accounting. Hydrological accounting, also known as water balance, is a systematic numerical budget of moisture inflow, outflow, and storage. Based on Palmer's definition, drought occurs when water supply is significantly less than potential supply (water needed for normal operation of the established economy). Palmer determined potential supply as the amount of precipitation that is climatically appropriate for existing conditions (CAFEC) at a given place and time. The difference between the actual precipitation and the CAFEC precipitation is the deficit (negative) or surplus (positive). If $P_{i,j}$ is the actual precipitation in month j ($1, 2 \dots 12$) in year i ($1, 2 \dots n$), and $\hat{P}_{i,j}$ is the CAFEC precipitation equivalent, then the difference:

$$d_{i,j} = P_{i,j} - \hat{P}_{i,j} \quad [1]$$

is the deficit (surplus) for the time and place. It is the basic variable used for constructing the index. Palmer used the water balance equation to determine $\hat{P}_{i,j}$.

Water Balance Equation

The water balance equation for a natural surface is represented as:

$$P = ET + R + RO \quad [2]$$

where P is precipitation, ET is actual evapotranspiration, R is moisture storage in the soil (recharge), and RO is surface runoff. Actual evapotranspiration is the combined moisture loss to the atmosphere from vegetation and soil. In climatology, eqn [1] assumes the following sequence in the destination of precipitation: (1) loss to the atmosphere up to full atmospheric demand; (2) storage in the soil (soil water recharge) until filled to capacity; and (3) surface runoff – water transported over land – after sequence steps (1) and (2) are completed.

The term potential evapotranspiration (PE), also called atmospheric demand, is the maximum amount of water lost to the atmosphere through evapotranspiration under the existing atmospheric condition. PE is achieved only when water from precipitation, soil storage, or both is enough to enable it. When water from the two sources is less than PE, a deficit occurs.

Palmer's use of the water balance equation

Palmer used monthly data for mean surface temperature and precipitation to solve the water balance equation in monthly time steps. The Thornthwaite method (Thornthwaite, 1948) was used to obtain potential evapotranspiration from mean monthly temperature. All precipitation was treated as rain. Snowfall was cumulated over the winter and its rainfall equivalent added to the soil in the spring. Palmer made several assumptions concerning soil moisture storage and its usage. The soil was divided into two layers. The top layer (Layer 1), roughly equivalent to plow depth, was assumed to contain 25 mm of available water (AW) at field capacity. Field capacity is the maximum volume of water the soil holds when fully drained of excess water. AW is the amount of moisture held in the soil between field capacity and wilting point (the minimum plant-extractable soil moisture content). Palmer assumed that the equivalent capacity for the second (underlying) layer (Layer 2) is site specific. All moisture is removed from Layer 1 before any is taken from 2. Withdrawal from the underlying layer is subject to increasing resistance as the

moisture level is drawn down. Palmer assumed that the rate of withdrawal is a function of potential evapotranspiration and of the ratio of the water content in that layer to the combined available water holding/moisture capacity (AWC) of both layers. The water balance over a crop at a specified time step is set up as follows. Input is precipitation. Crop water demand is potential evapotranspiration. If precipitation exceeds PE, actual evapotranspiration $ET = PE$ (Figure 2). The difference $P - PE$ is stored in the soil (recharge) up to field capacity. Runoff occurs after full soil recharge. If precipitation is insufficient to satisfy PE, water is drawn from the soil layers as specified here until PE is achieved. When that happens, $ET = PE$. However, if after withdrawal, water is still insufficient to satisfy PE, the actual evapotranspiration (ET) is the sum of precipitation and soil withdrawal and ET is less than PE. The difference $PE - ET$ is the deficit (Figure 2). A surplus (runoff) occurs when precipitation exceeds the sum of potential evapotranspiration and amount of moisture required to bring the soil to field capacity. Equation [2] is reformulated to accommodate the exchanges discussed here:

$$ET = P - R - RO + L \quad [3]$$

where L is loss from the soil (water withdrawal from storage).

Palmer's challenge was to:

1. adapt data derived from eqn [3] for use within his CAFEC environment;

Figure 2 A water balance flow chart.

2. establish a numerical scale for the assessment of drought (wet period) severity based on the water balance (this water balance-based scale is the Palmer hydrological index (PHDI));
3. determine the onset and end of a drought (wet period); and
4. refine the PHDI to improve its meteorological sensitivity. The refined product, which includes a mechanism for determining the onset and end of a drought (wet period), is the PDSI.

The steps taken to meet the challenge and the supporting arguments are covered in Sections [Determination of CAFEC Values](#), [Calculating the Palmer Hydrological Drought Index](#), [Ending a Drought \(Wet Period\)](#), and [Palmer's Meteorological Drought Severity Index](#).

Determination of CAFEC Values

Palmer utilized several variables to calculate CAFEC precipitation $\hat{P}$ for a region. In addition to PE, ET, R , RO, and L , he introduced three new ones, namely, potential recharge (PR), potential loss (PL), and potential runoff (PRO). The term 'potential' refers to the expected normal for the region. The physical meaning of the additional terms is given in [Table 1](#).

Palmer used the variables to derive four coefficients: α is the coefficient of evapotranspiration, also referred to as the coefficient of climatically appropriate moisture efficiency; β the coefficient of recharge; γ the runoff coefficient; and δ the coefficient of loss.

$$\alpha_j = \overline{ET_j}/\overline{PE_j} \quad \text{if } \overline{PE} > 0, \alpha_j = 1 \text{ otherwise} \quad [4]$$

$$\beta_j = \overline{R_j}/\overline{PR_j} \quad \text{if } \overline{PR_j} > 0, \beta = 0 \text{ otherwise} \quad [5]$$

$$\gamma_j = \overline{RO_j}/\overline{PRO_j} \quad \text{if } \overline{PRO_j} > 0, \gamma_j = 0 \text{ otherwise} \quad [6]$$

$$\delta_j = \overline{L_j}/\overline{PL_j} \quad \text{if } \overline{PL} > 0, \delta_j = 0 \text{ otherwise} \quad [7]$$

In eqns [4]–[7], an overbar denotes monthly means obtained over the years of data.

Based on these calculations, Palmer reformulated eqn [3] to obtain the CAFEC precipitation for a place:

$$\hat{P}_{ij} = \alpha_j PE_{ij} + \beta_j PR_{ij} + \gamma_j PRO_{ij} - \delta_j PL_{ij} \quad [8]$$

CAFEC precipitation for a given month may differ from the long-term mean. If the preceding months have been hot and dry, the stored moisture will be nearly depleted, and CAFEC

precipitation, as well as water demand, will be high. The difference between actual precipitation and CAFEC precipitation d_{ij} will be negative with a high absolute value, as the deficit with respect to demand may have been much greater than the deficit with respect to the long-term average precipitation. Similarly, above normal precipitation in a month when the soil moisture is at capacity and PE is low will show as a greater surplus than if the soil moisture had been close to depletion and PE was high.

Palmer further recognized that two regions with the same deficit might not suffer identical economic consequences if they had different moisture supply bases. The region with the lower supply base will be more stressed. To discriminate with respect to differences in impact over the two regions, Palmer calculated k_j , the ratio of the mean demand to the mean supply for a given place and month, which he used to adjust the d_{ij} to reflect the disparity arising from differences in supply. Thus:

$$k_j = (\overline{PE_j} + \overline{R_j})/(\overline{P_j} + \overline{L_j}) \quad [9]$$

The moisture anomaly index z_{ij} was formulated to provide the desired spatial weighting for d_{ij} :

$$z_{ij} = d_{ij} k_j \quad [10]$$

Calculating the Palmer Hydrological Drought Index

Generally, droughts become more severe the longer they last. Thus, cumulative plots of z at a place not only capture the magnitude of an event but also reflect its duration. Based on similar cumulative plots over two locations, Palmer determined that drought severity could be adequately represented by four distinct classes (mild, moderate, severe, and extreme) to which he assigned values based on his cumulative plots ([Table 2](#)). The four classes of drought were separated from the opposite classes of wetness by normal conditions. Palmer reconciled the effect of intense short-period deficits against those produced by less intense but longer-lasting ones by considering maximum rates of accumulation of z at different stations. He concluded that the accumulation of z at a rate of -12.0 for 1 month or -85.0 over 60 months would constitute extreme drought. He used this argument to derive a quantitative expression for drought severity X_g :

$$X_g = \sum_{j=1}^g \frac{z_{ij}}{0.309j + 2.691} \quad [11]$$

Table 1 Partial list of variables for computation of Palmer's CAFEC precipitation

Symbol	Description	Physical meaning
PR	Potential recharge	Amount of water needed to bring the soil to field capacity
PRO	Potential runoff	Total amount of soil moisture storage available
PL	Potential loss	Amount of water that could be lost from the soil if no precipitation occurred during the month

Table 2 Palmer drought severity index for moisture conditions

Index value	Moisture condition
Less than -4	Extreme drought
-3.0 to -4.0	Severe drought
-2.0 to -3.0	Moderate drought
-1.0 to -2.0	Mild drought
-1.0 to 1.0	Normal condition
1.0 – 2.0	Mild wet spell
2.0 – 3.0	Moderate wet spell
3.0 – 4.0	Severe wet spell
Greater than 4.0	Extreme wet spell

where g is the target (current) month and $j = 1, 2, \dots$ (eqn [11]) accumulates weighted values of z beginning with the first month ($j = 1$) of drought (wet period) to the target month ($j = g$).

Recognizing that a single very dry or very wet month in a long series of months with opposite moisture conditions may unrealistically reflect in the severity value, Palmer revised eqn [11] to include each month in the index in an incremental basis. The revised equation:

$$X_g = 0.897X_{g-1} + Z_g/3 \quad [12]$$

accomplishes two things. First, the duration factor is included implicitly through the sequentially arranged values of X . Second, the severity index acquires a memory through the recursive term X_{g-1} , the previous month's severity.

Based on eqn [12], the values of X_g will range from greater than +4 (very much wetter than normal) to -4.0 (very much drier than normal, or extreme drought) with values close to zero constituting near-normal conditions.

Reevaluating the Spatial Weighting Factor

Palmer's formulas were created with data from Kansas and Iowa. When applied to other climatic regions, the original expression for spatial weighting produced unrealistic values. This discrepancy led Palmer to modify his approach to spatial weighting. He assumed that for a given area, the driest 12-month period on record represents extreme drought. He next determined that the accumulated $z_{i,j}$ value, which would yield $X = -4.0$ from eqn [12], was -25.60. A new value of the 12-month mean weighting factor $\bar{K}$ could then be determined by dividing the 12-month sum of $d_{i,j}$ for the driest 12 months on record by -25.60. By experimenting with several stations outside Iowa and Kansas, he found that values of $\bar{K}$ based on long-term records varied from 1.06 in humid areas to 1.73 in drier ones. From this, he concluded that $\bar{K}$ and its monthly equivalent K_j depend on average water supply conditions, as did the k values. This led Palmer to further modify his approach to regional weighting by adding average runoff to the moisture demand term. He discovered that with this inclusion, $\bar{K}$ varied inversely with $\bar{D}$, the mean of the absolute values of $d_{i,j}$. Plotting all his experimental values on a graph, he concluded that a new monthly weighting value

$$K_j = 1.5 \log_{10}\{(S_j + 2.8)/D_j\} + 0.50 \quad [13]$$

where

$$D_j = \sum_{i=1}^n (|d_{ij}|)/n \quad [14]$$

and

$$S_j = (\overline{PE_j} + \overline{R_j} + \overline{RO_j})/(\overline{P_j} + \overline{L_j}) \quad [15]$$

improved the spatial adjustment factor k_j . The final form of the spatial weighting factor became

$$K = 17.67K' / \left(\sum_{j=1}^{12} \overline{DK'} \right) \quad [16]$$

Following the modifications, a new set of values $Z_{i,j}$ was calculated to define moisture anomalies normalized with respect to both time and space:

$$Z_{ij} = K_j d_{ij} \quad [17]$$

which replaced the $z_{i,j}$ in eqn [10]. The X_g calculated with the new $Z_{i,j}$ was Palmer's first approximation to his drought severity index and is often considered the PDSI by many researchers and used as such. However, at this point the index could more properly be considered a hydrological drought index (PDHI) since it consists basically of the systematic moisture budget referred to in the Section [Drought as Defined by Palmer](#).

Ending a Drought (Wet Period)

A wet period or drought is considered to have ended when X_g approaches zero. At that point, moisture demand is satisfied. But it may not endure. A return to normal weather following readjustments of large-scale or regional-scale atmospheric circulation patterns will have to persist much longer in order for this index to truly reflect a return to normal conditions. Therefore, in meteorological terms, the criteria for ending a drought (wet period) are more stringent than for achieving X_g close to 0. Consequently, another method is needed to establish the beginning and ending of dry and wet periods. Also, requiring the severity index to drop all the way to zero or near zero could result in an unjustified perception that a mild drought persisted over many years if followed by slightly dry or even normal weather. However, if the drought index was required to reduce to only -1.0, a single normal month could lead to a premature end of a mild drought that could still evolve into a severer one.

Palmer conceded that drought would most reasonably have ended with the index somewhere between -1.0 and 0.0, and chose -0.5. Thus, as the index reaches the 'near-normal' category and the drought or wet spell is considered terminated, Palmer then asked the question of how much moisture would be required to reduce the index value to -0.5. Allowing X_g to equal -0.5, Palmer solved for this value, which he assigned the symbol Z_e ,

$$Z_e = -2.6619 X_{g-1} - 1.50 \quad [18]$$

for a dry spell, and

$$Z_e = -2.6691 X_{g-1} + 1.50 \quad [19]$$

for a wet one.

Also, there is some smallest value of Z , which could occur month after month and produce X_g equal to -0.5. In such cases, using eqn [11], ΔX would be zero, $X_g - 1$ would be -0.5, and Z_g would be -0.15. This value indicates that a drought may end even if the weather is consistently slightly drier than normal. Therefore, once a drought has definitely begun ($X_g \leq -1.0$), any value of Z greater than -0.15 should end it. Palmer could then answer the question that he posed by calculating U_w , or effective wetness, which would apply *only* once $X_g \leq 1.0$.

$$U_w = Z_g + 0.15 \quad [20]$$

Assume that for month g , $X_g \leq -1.0$. If, during that month, the amount of wetness required to end the drought is greater than the effective wetness ($Z_e > U_w$), the drought severity index will be lower than for month $g-1$, but the drought will not have ended. However, the amount of wetness required to end the drought during the following month, $g+1$, will have been diminished by the accumulated wetness such that a new value of Z_e must be calculated.

To enable that calculation, Palmer redefined Z_e . If $x_j \leq -1.0$ for all months h from h^* , the first month of the drought through g , the current drought month, then for month g ,

$$Z_{e_g} = Z_{e_{(g-h)}} + \sum_{h=0}^{h=h^*} (U_{(g-h)} - U_g) \quad [21]$$

U_g is U_w in month g and $h^* \leq h \leq g$. The drought duration is $(g - h^* + 1)$ Z_e computed for month g during any dry spell then represents that amount of wetness needed to end the drought in that month. The value U_g for the month g is the effective wetness, the amount that actually occurred. By keeping track of accumulated values of U as well as the current Z_e , Palmer was able to determine a percentage probability Pe_g that a drought has ended in month g . Pe_g is not a true stochastic probability but rather a ratio of the amount of moisture received in month g to that required to end the drought in that month, expressed as a percentage. Pe_g is formulated as follows:

$$Pe_g = \left(100 \sum_{h=0}^{h=h^*} U_{g-h} \right) / \left(Z_e + \sum_{h=1}^{h=h^*} U_{g-h} \right) \quad [22]$$

where $h^* \leq h < g$.

This probability may then be used as a basis for defining drought ending times, particularly when the physical sense of the index is ambiguous.

Palmer's Meteorological Drought Severity Index

Once a method for defining the ending of droughts and wet spells was established, Palmer further refined the index to make it more sensitive to meteorological conditions. The final product with the added meteorological sensitivity is the true PDSI. He accomplished this by keeping track of all the previous dry and wet spells using three different indices: $X1_{ij}$, the severity index of a wet spell that is becoming established; $X2_{ij}$, the severity index for a dry spell that is becoming established; and $X3_{ij}$, the severity index for any wet or dry spell that has become established. The three indices are calculated as follows:

$$X1_g = 0.897X1_{g-1} + Z_g/3 \quad \text{if } X1_g > 0; \text{ otherwise } X1_g = 0 \quad [23]$$

which gives positive and nonzero values for wet spells, and

$$X2_g = 0.897X2_{g-1} + Z_g/3 \quad \text{if } X2_g < 0; \text{ otherwise } X2_g = 0 \quad [24]$$

which gives negative and nonzero values for any dry spell.

If $Pe_g < 100$, then

$$X3_g = 0.897X3_{g-1} + Z_g/3 \quad [25]$$

Otherwise, $X3_g = 0$, which gives nonzero positive or negative values only when the probability of ending the current wet or dry spell is less than 100%.

Equations [23]–[25] follow definitions of the three indices. However, assigning a value to $X3$ for the beginning of an established wet or dry spell requires changing from one index to another, as follows:

$$\text{If } X3_g = 0 \text{ and } X1_g > 1 \text{ then } X3_g = X1_g \quad [26]$$

Equation [26] indicates that a wet spell has become established for the first time. Similarly:

$$\text{If } X3_g = 0 \text{ and } X2_g < -1 \text{ then } X3_g = X2_g \quad [27]$$

Equation [27] identifies the start of a dry spell.

To assign a value to the actual meteorological index (i.e., the PDSI_g for month g), one of the three indices defined in eqns [23]–[25] must be chosen. In some cases, the procedure is straightforward, but in others, confusion may arise. Palmer used examples from a long-running data set from western Kansas to demonstrate whether the assigned value represents the beginning of an established wet spell or a dry spell. When Pe drops to zero, the PDSI value for that month is the $X3$ value. When Pe is 100%, the current spell has ended, and the PDSI value will have the value of $X1$ or $X2$, whichever is opposite in sign from the spell that just ended. Problems arise when Pe is between 0 and 100 and when both $X1$ and $X2$ have absolute values less than 1.0, indicating that no serious wet or dry spell is underway. Palmer's solution is to continue assigning values to both the $X1$ and $X2$ indices according to the criteria established in this article, but delay assigning a value to PDSI until $X1$ and $X2$ become zero at some future month. If $X2$ drops to zero first, then the $X1$ value is given to the unassigned cases, and a mild wet spell is considered to have occurred. Palmer himself considered this method to be a compromise. However, to calculate the PDSI through Palmer's method during times when both $X1$ and $X2$ are indicating low absolute values requires backtracking and, very occasionally, subjective decisions. While this does not present major problems when working with fewer than 10 data sets listed in tabular format, difficulties encountered when electronically processing scores of sets have led to a number of modifications. For example, the *Weekly Weather and Crop Bulletin* assigns values to PDSI_g based on Pe_g , $X1_g$, $X2_g$, and $X3_g$ as follows:

$$1. \quad \text{If } 0 < Pe_g \leq 50, \text{ then } PDSI_g = X3_g \quad [28]$$

This constraint covers the case when $X3$ is nonzero, and a wet or dry spell has been established, but the probability of the spell ending, while not zero as yet, is low. Had this constraint been applied to Palmer's western Kansas example, one 8-month dry spell would have lasted 10 months:

$$2. \quad \text{If } 50 < Pe_g < 100, \text{ then } PDSI_g = X1_g \text{ or } X2_g \quad [29]$$

whichever results in an index having the opposite sign from $X3_g$. This change in sign would indicate a switch from a dry to a wet spell or from a wet to a dry spell.

The drought-ending criterion is as follows: once the probability of ending the wet or dry spell exceeds 50%, the value of $X1$ or $X2$, which would indicate a change of weather conditions, is used as the PDSI value. Had this been used in Palmer's

example, one 4-month near-normal wet spell would have been a 3-month near-normal wet spell followed by a single near-normal dry spell.

$$3. \text{ If } X_{3g} = 0, \text{ then } PDSI_g = X_{1g} \text{ or } X_{2g} \quad [30]$$

whichever has the larger value. Through this criterion, the case of $P_e = 100\%$ is covered, as X_{3g} would in that case be zero. Also, since the constraint of $X_{3g} = 0$ means that the absolute values of X_{1g} and X_{2g} are both less than 1.0, the case in which Palmer required backtracking and occasional arbitrary decisions is resolved. Had this criterion been applied to Palmer's example, the results would be unchanged.

Criticism of the Palmer Index

The PDSI has been criticized for various reasons. Alley (1984) and Karl and Knight (1985) listed the following issues, which are deemed drawbacks:

1. The values quantifying the intensity of drought and signaling the beginning and end of a drought or wet spell were arbitrarily selected based on Palmer's study of central Iowa and western Kansas and have little scientific meaning.
2. Because the Index is sensitive to the available moisture capacity (AWC) of a soil type, applying it to a climate division may be too general.
3. The two soil layers within the water balance computations are simplified and may not be accurately representative of a location.
4. Snowfall, snow cover, and frozen ground are not recognized in the Index. Since all precipitation is treated as rain, the timing of PDSI or PHDI values may be inaccurate in the winter and spring months in regions where snow and frost occur.
5. The natural lag between when precipitation falls and the resulting runoff is not considered. In addition, no runoff is allowed to take place in the model until the water capacity of the surface and subsurface soil layers is full. This could lead to an underestimation of runoff.
6. Potential evapotranspiration is estimated using the Thornthwaite method. While this technique has wide acceptance, it is still only an approximation.

Whereas these comments and criticisms have earned respect within a large section of the scientific community, there is also widespread support for Palmer's approach and methodology. What follows reflects the views of the latter group.

Palmer may have 'arbitrarily' tuned his model to obtain agreement with observed data from Kansas and Iowa, but model tuning is widely used in science to enhance robustness. The accusation of arbitrariness appears extreme given his meticulous argumentation and inclusion of data from several climatically diverse regions outside the two states. Successful results achieved with the model in many world regions have given it added credibility. As well, work aimed at overhauling Palmer's criteria for the onset and end of droughts and wet periods has produced very modest improvements (see Section [Palmer's Meteorological Drought Severity Index](#)). The issue concerning snow and AWC would be serious if the index

was constructed as a short-term moisture status indicator. However, because Palmer targeted the longer term (months to years), time lag between input and output (snow, soil moisture change, and runoff) is not a significant factor in Palmer's drought scaling and timing (Weber, 1996). Even though more theoretically based models normally yield better potential evapotranspiration data, van der Schrier et al. (2006) show that PDSI estimates computed with the Penman-Montieth and Thornthwaite methods are very similar. Dai et al. (2004) reported significant agreement between observed soil moisture and Palmer model-based equivalents in the United States, Mongolia, China, and the former Soviet Union.

Current Applications

The PDSI is widely used as an environmental moisture indicator. Historically, the PDSI was used to classify, map, and interpret past drought events. While it still serves those purposes, today it is increasingly used in a forecast mode. For example, Drought Monitor, an organization comprising federal and state agencies, universities, and the private sector, provides monthly forecasts of moisture conditions in the United States based on the Index. The US National Oceanic and Atmospheric Administration publishes weekly Palmer maps. PDSI is also used to reconstruct past droughts at geological time scale based on temperature and precipitation derived with dendrochronology. Such reconstructed drought patterns have been used to explain the emergence and collapse of civilization, including the demise of the Bronze Age. Historical patterns of soil moisture derived through the Index help inform the contribution of soil moisture to global warming.

Conclusion

Palmer's drought index fulfills most of the criteria specified for an ideal index. Perhaps his most important contribution to moisture scaling is giving quantitative expression to differing thresholds for drought across regions as well as land use and economic practices. While the assumptions may appear too numerous and simplistic to some scientists, several experiments designed to test them have either confirmed the robustness of Palmer's approach or suggested modifications that are not significant enough to alter the fundamentals of his methods. But changes are being made and will continue to be made in how data are acquired and processed for PDSI. Remote sensing enables data acquisition from large geographical areas at high frequency. Several software packages are available for computing the index for various time and spatial scales. Used within a Geographical Information System environment, the PDSI can facilitate spatial and temporal analyses of drought pattern anywhere. Although the PDSI has been used primarily to study past drought events, its use as a forecasting tool for future events is expanding. The flexibility offered by the CAFEC concept makes it an ideal tool for constructing water budget scenarios for climate change impacts.

Soil Moisture

Synopsis

Soil moisture is an important variable in the climate system. Understanding and predicting variations of surface temperature, precipitation, drought, flood, and the impacts of future climate change depend critically on knowledge of soil moisture variations. There are few long-term observations of soil moisture. Remote sensing of soil moisture is in its infancy and can observe only the wetness of the top centimeter or two of soil. The production of a global soil moisture data set will require an excellent land surface model and data assimilation system, validated with observations, that calculates soil moisture based on soil moisture observations and observations of precipitation, temperature, insolation, and other weather variables.

Introduction

Soil moisture is the amount of water in the active layer of the soil, typically the top 1–2 m. Soil moisture is extremely important because it is the main source of water for agriculture and natural vegetation. Near-surface soil moisture also controls the partitioning of available energy at the surface into sensible and latent heat exchange with the atmosphere, thus linking the water and energy balances through the moisture and temperature states of the soil. Soil moisture is the source of water that evaporates and transpires from the soil and vegetation into the atmosphere, thus affecting the distribution of clouds and precipitation. Surface temperature is controlled by soil moisture, as a wetter surface will be cooler, with more of the available energy going into evapotranspiration (evaporation and transpiration) rather than heating the surface. Soil moisture also affects runoff, determining how much precipitation or snowmelt goes immediately into rivers and streams, or in extreme cases into flooding. A deficit of soil moisture is often connected to 'drought,' and soil moisture interactions with the atmosphere may be important in maintaining droughts. Soil moisture, along with snow cover, is also the most important component of meteorological memory for the climate system over the land. Thus, the soil moisture state is an important predictor of monthly to seasonal climate variations.

Soil moisture is measured in a variety of ways, from the simple gravimetric technique to more complex electronic instruments. For the top 1 m soil layers, the temporal scale of soil moisture variation in the Northern Hemisphere midlatitudes is 1.5–2 months and the spatial scale is about 500 km. Despite the importance of soil moisture, parameterization schemes used in weather forecast and climate simulation models, in general, do not capture the observed soil moisture variations when forced with either model-generated or observed meteorology. During the twenty-first century, a significant vulnerability for human society may be summer drying in the subtropics and midlatitudes. Observations of summer soil moisture variations for the past several decades, however, show that for the stations with the longest recorded summer, soil moisture in the top 1 m has increased while temperatures have risen. In Eastern Europe, where these observations were taken, increasing tropospheric pollution following World War II produced solar dimming, reducing the

evaporative demand at the surface. This effect dominated any trends in temperature or precipitation.

Definition of Soil Moisture

The term 'soil moisture' refers to the amount of water in the upper layer of soil that interacts with the atmosphere. This varies depending on soil type and vegetation, but is typically about the top 1 m. Soil moisture can be expressed in different units. The most common are as plant-available volumetric soil moisture (W) or as total volumetric soil moisture (W_T), expressed as the depth of a column of water contained in a given depth of soil, or as the volumetric percentage of water in a given soil depth. A fraction, typically less than half, of soil consists of pores that can be filled with air or water. This fraction is called the *porosity* (P). If this fraction were completely filled with water, the soil would contain its *total water-holding capacity* (W_o), and the water table would be at the surface. For any layer of depth (thickness) D , $W_o = PD$. If the soil were saturated, so that $W_T = W_o$, and then gravitational drainage were allowed to occur until it was negligible, the amount of water left in the soil is called the *field capacity* (W_f). If vegetation then extracted as much water as possible until it wilted, the remaining soil moisture is called the *wilting level* (W^*), and this amount of water is unavailable to plants. The plant-available soil moisture is $W = W_T - W^*$.

Measurement of Soil Moisture

There are many different techniques to measure soil moisture. The choice of a particular method depends on the application and the resources available. Here, the principal techniques are briefly described.

Gravimetric

The gravimetric method, also called the thermostat-weight technique, has been in use for a long time. Soil samples are taken using coring devices or augers at required depths and locations. Typically (in the Russian method), 10 cm segments reaching a depth of 1 or 1.5 m are extracted and a smaller

sample is removed from each segment. The sample is weighed, oven-dried, and weighed again. The difference in mass gives the total soil moisture in the sample, which is converted to volumetric units using the density of the soil. The wilting level is then subtracted, giving plant-available soil moisture, expressed as depth of liquid water.

Under the leadership of the State Hydrological Institute, the Russians established a system of soil moisture observations throughout the former Soviet Union. The network consisted of several thousand stations using the gravimetric technique. Typically, samples are taken at four different locations at a station each 10 days. After 10 days, the cores are replaced in the holes and samples are taken from other holes. In this way, after some time the effects of sampling disappear and the same location can be reused. In very cold regions, observations were taken either once a month or not at all. Other countries that were influenced by the Soviet Union also set up soil moisture observation programs, and extensive data sets now also exist for China and Mongolia.

The gravimetric method is low-tech and simple, making it an excellent technique for long homogeneous climatological records. As it is labor-intensive and somewhat destructive to its site, new electronic methods are being introduced that are indirect and require calibration and theoretical assumptions. With suitable parallel measurements, the new methods can produce useful long records, and they are briefly described in this article. However, all the electronic methods suffer from some problems and require extensive calibration with gravimetric measurements that span the time scales of the seasonal cycle and interannual variations. Furthermore, hysteresis effects may give ambiguous readings, and some techniques may be less accurate in certain soils and for extremely dry or wet soil.

Neutron Probe

The neutron probe is relatively easy to use, accurate, and capable of measurements in real time. A probe with a fast neutron source is placed on the surface or lowered in an access tube (transparent to the neutrons), and the back-scattered slow neutrons are measured. The back-scattered flux of slow neutrons is proportional to the density of hydrogen atoms. Water is the major source of hydrogen atoms that changes with time; therefore, the neutron probe provides a good measure of soil water content. Calibration of slow neutron counts with gravimetric samples of soil moisture content and bulk densities yields a relationship to estimate the volumetric soil moisture content. Since radioactive scattering occurs over a spherical domain, a neutron probe samples a volume of soil rather than a point. As this volume of influence depends on soil moisture content, there are differences in the soil volumes sampled in dry and wet soils. These differences are generally small as compared to the total volume sampled by the probe, but they influence the depth resolution of the probe. The probe's relatively large volume of influence makes observations at shallow depths prone to errors, as adjoining air is also sampled. Disadvantages of neutron probes include that they are also labor intensive, the need for precautions associated with handling radioactive material, and the relatively high costs. An extensive data set of soil moisture observations from Illinois

starting in 1981 was made with neutron probes, with observations made 2–3 times per month year round.

Heat Dissipation Sensors

These sensors make point measurement of soil moisture tension by measuring temperature changes in response to a heat pulse. A small ceramic block with an embedded sensor is briefly heated. The rate of heating is affected by the ability of the ceramic block to dissipate the heat. This is related to its soil moisture content, which has equilibrated with the surrounding soil. The measured heating rate must be calibrated, and soil moisture tension related to volumetric water content, by gravimetric observations for each location or with theoretical relationships. These sensors are relatively inexpensive and can produce measurements every 30 min. An extensive network in Oklahoma and Kansas now uses these sensors. Once installed and calibrated, a very labor-intensive effort, an advantage of these sensors is that they are automatic and can take observations of both soil temperature and soil moisture with high temporal resolution.

Other In Situ Sensors

Other in situ soil moisture measurement techniques include the tensiometer (a bulb of porous ceramic material is placed inside the soil and connected to a water-filled tube, which is used to measure soil moisture tension after allowing the system to equilibrate), the gypsum block (small cylindrical gypsum blocks embedded with electrodes are buried at required depths in the soil and measure the electrical resistance, which is related to the water content), time domain reflectometry (TDR; based on monitoring changes in the dielectric properties of the soil at microwave frequencies), frequency domain reflectometry (FDR; similar to TDR, except that it derives soil moisture content based on changes in the frequency of signals due to the dielectric properties of the soil), and gamma densitometry (based on the relatively greater gamma radiation attenuation factor of water compared to other soil components). Each technique has limitations and advantages.

Remote Sensing of Soil Moisture

If radiance or gamma rays from soil moisture can be observed above the soil and related to the soil moisture, using gravimetric observations for calibration, then remote sensing can be used over a much larger region than in situ observations. Satellites have the potential to produce global soil moisture observations, but such observations are restricted to the top few centimeters of the surface. Reflections of global positioning system (GPS) signals using GPS sensors mounted near the ground or measuring cosmic rays from a sensor mounted near the ground have the potential for measuring a deeper layer (up to 50 cm) over a small area near the sensor.

Satellite remote sensing of soil moisture

Satellite remote sensing of soil moisture works on the principle that microwave emissions from the soil depend on the soil moisture because of the large difference in dielectric constant between dry and wet soil. However, the emission also depends

Figure 1 Average seasonal cycles of soil moisture, averaged for the entire length of each data set (Figure 2). Units are centimeters of water in the top 1 m, except the top 60 cm for India. The shape depends on the seasonal cycles of precipitation and evapotranspiration. For those regions where optimal averaging was used, whiskers indicate the estimated one standard deviation error range associated with the spatial distribution of the stations. Copyright 2000 American Meteorological Society.

on surface roughness, surface temperature, and vegetation, so ancillary information is needed, and remote sensing under a dense canopy is not possible. The longer the wavelength of the radiation, the deeper the potential signal. Typically, C-band (frequency ≈ 6 GHz, wavelength ≈ 5 cm) and L-band (frequency ≈ 1.3 GHz, wavelength ≈ 23 cm) radiometers have

been used on satellites. L-band observations have the potential to sample more of the top few centimeters of soil but require larger antennas on the satellites. Passive observations have footprints several tens of kilometers across and repeat cycles of about 3 days, while active observations (radar) have smaller footprints but sample the ground much less frequently. The

most advanced satellite now measuring soil moisture is the Soil Moisture Ocean Salinity (SMOS) satellite that was launched by the European Space Agency in late 2009 and makes passive L-band measurements. NASA plans to launch the Soil Moisture Active & Passive (SMAP) satellite in late 2014, which will use both active and passive L-band measurements. By combining observations from different satellites and validating them with in situ observations, it is possible to monitor flood and drought regions and get useful information on the wetness of the soil surface. Visible and infrared radiation can also be used for indirect satellite soil moisture monitoring, but cannot make measurements when cloudy. Microwave remote sensing offers the most promise for future global data sets but will have to be combined with validated land surface models using data assimilation to produce soil moisture fields for the entire active soil layer.

GPS soil moisture observations

GPS satellites transmit L-band signals that are used for navigation. By comparing the direct microwave signal received at a GPS receiver mounted on a pole in an open field with the signal reflected from the ground, the soil moisture in the top several tens of centimeters can be measured. Since satellites pass over a particular location in different directions, soil

moisture can be observed in different directions from the receiver, and a 1000 m² region around the receiver can be sampled. This technique is currently being tested and has the potential to measure soil moisture anywhere that GPS receivers are installed near the soil for other purposes, such as geodetic observations. GPS receivers can also be installed on airplanes to measure large areas with the same technique.

The COsmic-ray Soil Moisture Observing System (COSMOS)

The intensity of low-energy cosmic-ray neutrons above the ground is inversely correlated with soil water content. By measuring these neutrons, it is possible to measure the average soil moisture to depths of 50 cm over a region of about 350 000 m². This system is now being tested and has the possibility of measuring soil moisture over large regions more easily than with in situ sensors.

Soil Moisture Variations

Scales of Temporal and Spatial Variations of Soil Moisture

It is well known that the complex topography of natural landscapes, with spatially variable vegetation and soil types, and gravitational drainage and infiltration of water after heavy

Copyright 2000 American Meteorological Society.

rains, is responsible for very small-scale spatial (tens of meters) and temporal (up to a few days) variability in the soil moisture field. This scale of soil moisture variation is of intense interest to hydrologists, who connect it to variations of the water budget within catchments. When studying climate change, however, a larger scale is of interest, driven by fields of precipitation and evapotranspiration. In addition to this small-scale component of soil moisture variability, analysis of spatial fields and time series of soil moisture observations in the Northern Hemisphere midlatitudes also finds a long-term (about 1–4 months) and large-scale (about 400–800 km) signal related to atmospheric forcing. The meteorological component of soil moisture field variability has been found in observations and later received theoretical explanation. For example, the temporal scale is equal to the field capacity divided by the potential evaporation. The spatial structure of actual soil moisture obviously depends on the distribution

of topography, soils, and vegetation on all scales, but the scale of soil moisture variations can be related to the scale of atmospheric forcing.

Climatology

Figure 1 shows the mean seasonal cycle from eight different regions where actual in situ soil moisture observations exist (Figure 2). For each region, optimal averaging was used to produce one value representative of the area. Optimal averaging takes into account the spatial scale of soil moisture, and it gives less weight to repeated information and more weight to independent information. This is particularly important when there is missing information at particular times producing a changing distribution of stations. It also produces an estimate of the error of the estimated average, which is also shown in Figure 1.

Figure 3 Trends of summer soil moisture from stations or regions with the longest records. Reproduced from Robock, A., Vinnikov, K.Y., Srinivasan, G., et al., 2000. The global soil moisture data bank. *Bulletin of the American Meteorological Society* 81, 1281–1299. Copyright 2000 American Meteorological Society.

Western Russia, Illinois, and Iowa show a typical midlatitude seasonal cycle in a climate with precipitation distributed uniformly throughout the year. Soil moisture is high in the winter, and when the snow melts in the spring, some of the water infiltrates into the soil producing the peak soil moisture for the year. At the end of the summer, when evapotranspiration exceeds precipitation, soil moisture falls to the annual minimum value. In the autumn, evapotranspiration falls and soil moisture increases until the winter. When the ground is covered by snow, there is less change in soil moisture. Vapor exchange and infiltration through cracks and wormholes are still important in frozen soils.

The seasonal cycle in eastern Asia, on the other hand, shows a different character, as there is a large summer precipitation maximum associated with the summer monsoon. In Mongolia, during the half-year for which we have data, soil moisture stays almost constant. The increased evapotranspiration is almost exactly matched by the increased precipitation. In India, where evapotranspiration is much larger, soil moisture falls from the end of the rainy season and reaches a minimum just before the onset of the summer monsoon precipitation.

Trends

Figure 3 shows the trends of summer (June, July, and August) soil moisture from the longest soil moisture time series available 10 years ago. Although all the stations or regions had an upward trend in temperature during the period (not shown), they all showed an upward trend in soil moisture. The longest record of observed soil moisture is from the Ukraine (Figure 4). Although there is no trend in precipitation or temperature, the summer soil moisture shows a strong upward trend (Figure 5). This is because, as mentioned in this article, rising tropospheric

Figure 4 Location of 25 soil moisture districts with 45 years of soil moisture observations, for the period 1958–2002. Each district has on average six soil moisture stations. Also shown is the 22–40° E, 46–52° N box used for averaging the observations and model simulations shown in Figure 5. Reproduced from Robock, A., Li, H., 2006. Solar dimming and CO₂ effects on soil moisture trends. *Geophysical Research Letters* 33, L20708. <http://dx.doi.org/10.1029/2006GL027585>. Copyright 2006 American Meteorological Society.

pollution following World War II led to solar dimming and less evaporative demand at the surface, which dominated any trends in temperature or precipitation.

Virtually, all general circulation model (GCM) simulations of the future climate show summer drying of the midlatitudes. This summer desiccation is caused by evapotranspiration going up faster than precipitation in a greenhouse gas-warmed world. Observations, however, do not show this effect yet. Better models (discussed in Modeling of Soil Moisture) and longer observational time series will be needed to decide whether this prediction is valid.

Modeling of Soil Moisture

For many purposes, including weather forecasting, accurate climate modeling, seasonal prediction, and water resource management, it is crucial to have accurate land surface models. The soil moisture component that is driven by atmospheric forcing may be modeled using routine meteorological observations at regular meteorological stations. Small-scale variability of the soil moisture field is unpredictable and appears as a stochastic process in this context. However, land surface schemes, whether driven by GCMs or by observations, currently do an imperfect job of simulating the mean seasonal cycle and interannual variation of soil moisture, when compared to observations.

Soil moisture (W) variations in the active soil layer can be calculated with the following equation:

$$\frac{dW}{dt} = P + M + WT - E - R \quad [1]$$

where P is liquid precipitation, M is snowmelt, WT is water table contributions, E is evapotranspiration, and R is runoff. Sources of water for the soil are rain, melting snow, and possible subsurface contributions from a rising water table. Soil moisture is lost by evaporation from bare soil, transpiration through plants, and runoff either from the surface or through subsurface drainage. The dependence of evapotranspiration on soil moisture is a function of soil moisture, incoming energy, and rooting depth. When the soil is close to saturation or very dry, when the incoming energy is low (such as in high latitudes), or when plants have a shallow rooting depth, soil moisture has only a small influence on evapotranspiration. Models of soil moisture changes differ in their treatment of evapotranspiration, runoff, snow, frozen soil, and water table. Some models also explicitly contain a parameter that gives a temperature threshold to separate incoming liquid precipitation from solid precipitation.

The first soil moisture schemes in GCMs were based on the Manabe bucket model with 15 cm field capacity, implicit vegetation, and runoff only with bucket overflow. More recently, models have been developed with explicit consideration of vegetation that account for canopy interception of a portion of the precipitation, and explicit stomatal resistance to transpiration. The latest models also incorporate fluxes of CO₂ and other gases as part of the plant and soil biology and physics. In the past, it was convenient to refer to bucket-type models with implicit vegetation as simplistic, and models with explicit consideration of vegetation as sophisticated, complex, and presumably more accurate. But these more

Figure 5 (a) Summer (June, July, and August) plant-available soil moisture in the top 1 m of soil, averaged separately for fields with winter cereals and spring cereals for the region 22–40° E, 46–52° N in the Ukraine (Figure 4). Solar dimming and CO₂ effects on soil moisture trends. *Geophysical Research Letters* 33, L20708. doi:10.1029/2006GL027585. Copyright 2006 American Meteorological Society.

complex models have so far not shown themselves to be more accurate than the simple ones in climate model applications. Runoff can also be modeled in a more complex manner, including partitioning a fraction of heavy precipitation into immediate runoff and subsoil drainage. Different models have different field capacities and rooting depths, and divide the soil into different numbers of vertical layers for temperature and soil moisture computations.

Weather forecast models now incorporate land surface schemes to predict latent and sensible heat fluxes from the Earth's surface, as well as the radiative balance. In the process, soil moisture and other hydrological quantities, such as runoff, are calculated. Archives of climate model-produced soil moisture, output from GCM runs, are also now becoming available. The soil moisture results from different types of simulations will be different, depending on the way the calculation was done. Some of these come from reanalyses of the global climate system, but the soil moisture calculations in these reanalyses so far do not conserve water, adding or subtracting moisture to make up for atmospheric model deficiencies. Therefore, it is important to not confuse actual observations with model calculations. If a soil moisture 'data set' is to be used to initialize a land surface scheme, then the 'data set' must be calculated with the same land surface scheme, even if the land surface scheme is known to produce a bias in soil moisture.

Otherwise, there will be spin-up problems with the model trying to adjust from the initial values to its own climatology.

The Global Soil Moisture Data Bank has been incorporated into the new International Soil Moisture Network, a data hosting facility for global in situ soil moisture measurements. A continually increasing collection of soil moisture observations may be accessed for free at <http://ismn.geo.tuwien.ac.at/>.

Synopsis

Land through its vegetation and soil exchanges with the atmosphere energy, water vapor, carbon dioxide, and other important trace gases. Absorption of solar energy is a major determinant of these exchanges. Both models and data are needed to describe these processes.

Introduction

Land is closely coupled to the atmosphere and the latter to oceans. This system is driven by the absorption of solar radiation, much of it is absorbed by the underlying land and ocean surfaces. Land has much lower capacity to store the thermal energy than the oceans, but rather raises its temperature until it adjusts to lose as much energy as it has received. The consequent fluxes are an important determinant of the day-to-day weather, e.g., clouds and thunderstorms, which are important factors determining climates over land. Properties of the overlying atmosphere are strongly controlled by the influences of underlying surfaces that it has previously been in contact with, so the climate at a particular location acts to average influences from elsewhere, i.e., the climate of near-coastal regions resembles that of adjacent ocean areas, whereas that of continental interiors depends on the absorption of solar radiation by the surfaces it has come in contact with.

The clouds that form when atmospheric water vapor condenses into water droplets substantially reduce the available solar radiation, but their cooling effect is compensated to some extent by their increase of downward thermal radiation. When clouds are able to form drops or crystals that grow large enough to fall, the resulting precipitation supplies water to the soil, and hence plants for their growth. The surplus that is not so used fills streams, rivers, ground water, and reservoirs, and is either captured for human requirements or delivered at the mouths of rivers to the ocean. Incident solar radiation provides the energy required to drive photosynthesis and hence assimilates carbon, and in doing so leads to plant transpiration. The

transpiration of plants provides much of the evaporative cooling of the land surface by the atmosphere in moist regions.

The winds, temperature, and moisture of the overlying atmosphere also strongly affect the land surface, and in turn are affected by the land surface. Describing these influences requires knowledge of the mechanisms by which the land surface balances the energy and water it receives.

How Does the Land Surface Absorb Solar Radiation?

Solar radiation absorbed by any surface is given by the product of how much solar energy is incident on that surface, depending on the direction of the Sun and the orientation of the surface relative to this direction, and the fraction of that incident radiation that is absorbed.

The amount of solar radiation absorbed at the surface determines in large part the climate over land and climate in general. On average for the Earth, it is in nighttime half the time, and during daytime, on average, the angle formed between a vertical line from the surface of the Earth and the Sun is 60° . Consequently, the daytime average sunlight received at the top of the atmosphere is half of that which a point receives when the Sun is directly overhead, and the day–night average is a quarter of that received from an overhead Sun. Solar radiation at the surface is additionally affected by greater removal of radiation by the atmosphere when the Sun is closer to the horizon. These geometric factors reduce the solar radiation received in high latitudes and in winter, and enhance the solar radiation received in the tropics and

in summer, hence largely determining the seasonal and geographic variations of climate.

Quantitative details of climate are also highly dependent on how the atmosphere responds to the seasonal and geographical variations of solar energy delivery. Clouds are the primary mechanism by which the atmosphere alters the reception of solar radiation by the land surface. In addition, solar radiation is attenuated by other smaller atmospheric particles, referred to as aerosols, and atmospheric gaseous absorbers, such as water vapor and ozone. The total net radiation that heats the land surface includes that of downward thermal emission from the atmosphere, also depending on clouds and water vapor, and is reduced by the upward emission of thermal radiation. This 'Earth' radiation depends on surface temperature but less so than the fluxes of energy from surface evaporation and dry sensible heat. Hence, in discussing the atmospheric radiative fluxes to the surface in the next section, we use the term 'total net radiation.'

The fraction of solar radiation that is reflected by a surface is referred to as its albedo. Because land consists of surfaces oriented in all directions, its albedo is not simply determined by the reflection from a single flat surface but also by how much of reflected light is absorbed by other surfaces. Leaves are so arranged that a plant canopy reflects less than half as much solar radiation as do individual leaves. The albedo of land surfaces, and especially those vegetated depends on the wavelength of the solar radiation. The solar radiation that plants use is essentially at the same wavelengths as those of human vision that is 'visible light.' Approximately half of solar radiation occurs at longer wavelengths than visible. These longer wavelengths have much higher albedos since they are not used for photosynthesis and otherwise may lead to overheating.

What Determines Turbulent Fluxes of Water and Heat from the Land Surface?

Besides its absorption of radiation, the land surface and its interaction with the atmosphere depends on other factors. Over the course of a day, some of the daytime heating can conduct downward into the soil and then be released again at night. Averaged over day and night, the net absorption of radiation is largely balanced by fluxes of energy that the land surface delivers to the atmosphere. The turbulent motions of air near the land surface determine these fluxes. Convection and mechanical mixing in turn determine the intensity of the turbulence. The latter is determined by the strength of surface winds and by the roughness of the surface. Positive net land surface heating normally occurs only during the day and leads to convection. It usually has small negative values at night.

The energy carried from the surface by water vapor corresponds to the energy that was required to evaporate the water from its liquid state at the land surface or equivalently to the energy that will be released when this water vapor is converted back to liquid form through the formation of clouds and precipitation. Dry atmospheric energy is transported upward by relatively warm air rising and cold air sinking, providing the intense daytime convection that generates the boundary layer turbulence needed to remove the energy supplied to the surface by daytime radiation. This flux of dry energy is proportional to

the difference between land surface temperatures (i.e., that of leaves and soil surface) and that of the overlying air. The flux of water vapor is likewise proportional to the difference between water vapor concentrations at the surface and that of the overlying air. Where materials at the surface are supplied with water, e.g., inside leaves and in moist soil, the consequent water vapor concentration depends only on temperature. How the land surface responds to a given amount of net radiation depends on how it divides the removal of this energy between evaporation and dry atmospheric energy flux. The ratio of dry atmospheric energy flux to energy carried by water vapor is called the 'Bowen ratio.'

The Bowen ratio depends on surface temperatures, the relative humidity of the overlying air, and various resistances to removal of water from the soil. In the extreme, if the surface is very dry so that there is very little or no water available to be moved into the atmosphere, then the Bowen ratio becomes very large. Conversely, the smallest Bowen ratios occur in warm areas when there are no limitations on the removal of water from the surface but the atmospheric relative humidity is low. This situation can only happen locally with conditions different from those of the surrounding land surface, since the consequent flux of energy will exceed that provided by net radiation and so depends on air energy carried to that point from elsewhere. Such conditions are referred to as the 'oasis' effect.

Temperature alone determines the Bowen ratio when surface air is at 100% relative humidity. Evapotranspiration can still occur provided the surface is heated to raise the concentration of water in the near-surface soil and inside plant leaves to values of atmospheric humidity larger than that of the overlying air. At larger temperatures, these concentrations increase substantially and the Bowen ratio is less.

In sum, the Bowen ratio of moist surfaces will be greater for colder temperatures and higher relative humidity. It is further increased by various surface resistances that affect only the movement of water vapor or affect it more than the movement of dry heat, e.g., when the surface soil is dry, water vapor must diffuse upward from deeper soil layers, and the rate at which this diffusion occurs may limit transport of water into the air.

Precipitation and hence soil moisture are normally accompanied by growth of plants. Hence, the fluxes of water vapor from the land surface to the atmosphere largely occur through extraction of soil water by roots and transport through plants and their leaves. This transport is called transpiration. Normally, with adequate soil moisture, plant leaves are the main obstacle to this movement of water and hence act as an important control on the Bowen ratio. A leaf normally has to contain water to maintain its structure, and if the roots cannot supply water as fast as it loses it, it wilts. Hence, its water loss can be a threat to its survival. The leaves lose water primarily through tiny holes called 'stomates.' Why do leaves have this stomatal loss mechanism for water and what determines the extent by which the stomates lose water? Leaves may benefit from the resulting evaporative cooling in warm regions where they may otherwise be threatened by thermal damage from high temperatures. However, the primary reason is an even more basic element of plant's requirements for growth and survival. The photosynthesis of plants uses light from the Sun to convert carbon dioxide to the carbohydrates and proteins needed for plant growth (some of which eventually become

our own food). This can only work if the plants receive, besides light, an adequate supply of carbon dioxide. The stomates pass carbon dioxide from atmosphere to the inside of leaves where it can reach the chloroplasts and be used. This function of the stomates, however, is in a somewhat delicate balance, controlled by the stomatal opening, with how much water is lost. If the net stomatal passageway to the atmosphere is too large, the leaves may lose more water than the soil can provide, whereas if it is too small, the leaf may be starved of carbon dioxide, at least relative to the light energy available to convert it to carbohydrate.

Plants and related aspects of the land surface exchange not only carbon dioxide but also other important gases with the atmosphere, as addressed in the next section.

What Determines the Fluxes of Carbon Dioxide and Other Gases to and from the Land Surface?

As concluded in the previous section, the flux of carbon dioxide into plants is closely linked to the transpiration by vegetation and hence to much of the flux of water from the land into the atmosphere. However, if this removal of carbon dioxide were simply one-way or unbalanced in its direction of removal, the atmosphere would become exhausted and no longer provide an adequate supply of this essential plant nutrient. This may not be such a far-fetched possibility, because the amount of carbon from carbon dioxide currently contained in land plants is as large as that held in the atmosphere, including the atmosphere over the oceans; and that stored in the soil, originating from plants, is considerably larger. Large amounts of carbon dioxide have been converted to fossil fuels at earlier times in the Earth's history. Indeed, currently accessible coal deposits have been estimated to hold over 10 times the carbon currently contained in the atmosphere, and these deposits may have formed when the atmosphere held several times as much carbon dioxide as it does now.

Even more carbon is held in the oceans than by land, mostly dissolved as bicarbonates and carbonates. This carbon in seawater eventually makes its way into limestone sediments, which through movements of the Earth's crust are returned to land and the atmosphere. Fortunately, the natural exchanges of carbon dioxide between land, atmosphere, and ocean are normally very close to being in balance with the land, in particular, acting to move as much carbon dioxide back into the atmosphere as it removes. Currently, land appears to take up more carbon dioxide than it gives back to the atmosphere in response to the extra carbon dioxide being supplied by the human conversions of fossil fuels back into carbon dioxide and consequent increases of atmospheric carbon dioxide. Hence the net removal of this excess carbon dioxide by land must be regarded as a very valuable ecosystem service, reducing the consequent climate change. Although we know much about how the land exchanges carbon with the atmosphere, our current understanding of the details of the net removal into land is sufficiently poor that we cannot accurately determine under what conditions this removal could cease or possibly reverse.

How does carbon dioxide removed from the atmosphere by plants return back to the atmosphere? The carbohydrates that the plants produce from photosynthesis are largely eaten. At

the cellular level the mitochondria present in all eukaryotic cells metabolize (that is oxidize) these carbohydrates, generating energy and carbon dioxide. This energy supplies the needs of the cell and so that of more complete organisms, and the carbon dioxide is returned to the atmosphere. In our bodies, this carbon dioxide is then exhaled from our lungs. Only about 1% of the carbohydrate energy from plants is metabolized by humans. What happens to the rest?

The plants themselves use about half of their carbohydrate energy stores both to convert the carbohydrates to more complex molecules such as proteins and fat compounds and to continuously repair complex molecules such as enzymes that tend to 'wear out.' Additional energy is needed by roots to facilitate their acquisition of soil nutrients either by directly powering the movement of soil ions or indirectly by feeding other soil organisms such as mycorrhizae that facilitate the movement of insoluble soil nutrients to the roots.

The carbon that the plants do not use themselves, and that is not harvested by humans or other animals, is delivered to the land surface and soils as dead plant materials. This dead plant material feeds many small to microscopic organisms, at the bottom of the food chain mostly bacteria and fungi, the ultimate decomposers of plant materials that are responsible for return of carbon dioxide to the atmosphere. All these biological processes are strongly controlled by the physical environment, the overlying atmosphere, the water provided by precipitation, and the supply of energy and warmth by the Sun.

Some of the carbon compounds contained by plants are oxidized directly by high-temperature combustion: that is, by fires. Human use of plant carbon for energy, human land management practices, and natural or accidentally started fires release comparable amounts of carbon dioxide, in total perhaps as much as 20% of that captured by plants on average. Natural fires are themselves a land process that strongly interacts with the atmosphere.

Besides carbon dioxide, numerous other important carbon compounds are exchanged between the land surface and the atmosphere. Especially important for climate is methane, which is emitted in places where there is very little oxygen, such as swamps and rice paddies. In addition, complex organic compounds are given off in copious amounts by leaves and contribute to enhancing regional levels of ozone and photochemical smog. Forest fires are an especially important mechanism for the supply of other complex organic materials to the atmosphere, including important aerosols.

Other elements important for living cells that are exchanged between land and the atmosphere include nitrogen and sulfur. The molecular nitrogen in the atmosphere is very inert to chemical change, but enough nitrogen must be supplied to the land surface in the form of nitrate or ammonium compounds to maintain this element in living cells. Ammonium compounds are generated naturally by nitrogen-fixing organisms that live freely in the soil or are attached to the root systems of some plants, such as the legume family. Much of the nitrogen supplied by soil to plants comes from the fast recycling of the nitrogen residing in plants, e.g., the leaves and roots that die and return carbon to the soil also return, nitrogen that is released by microbial processes along with the carbon.

Humans now add large amounts of ammonium and nitrate to the soils directly as fertilizers or indirectly as wet and dry

deposition of these compounds from atmospheric pollution. Although some sulfur moves from the land into the atmosphere, much more is initially put into the atmosphere by the combustion of fossil fuels and this is then deposited back to the land.

Land processes supply ammonia and oxides of nitrogen to the atmosphere, which are major elements in determining aerosols and atmospheric chemistry. Most of the ammonia comes from areas where it has been concentrated by human management practices, such as from feedlots and heavily fertilized fields. Bacteria convert soil ammonium to nitrate ions and other bacteria convert some of this to nitrous oxide that escapes to the atmosphere.

What Data Are Needed about the Geographical Variations of Land Properties to Determine Their Interaction with the Atmosphere?

Models of the Earth system that describe the interactions of the land with the atmosphere require not only the best efforts to solve equations for the processes reviewed above but also knowledge of the geographically varying properties of the land surface that determine these interactions. Many of these properties are generated by the models themselves, e.g., those involving the absorption of solar radiation, temperatures, and aspects of the hydrological cycle such as precipitation and soil moisture. However, some necessary features are more accurately observed than modeled, or are best treated by a combination of modeling and observations.

Some particularly important parameters that need to be constrained by observations are the land albedos and aspects of vegetation that control these properties of the soil and other aspects of the land surface that determine the movement of water and how much ends up in streams and rivers or escapes to the atmosphere. The latter include the roughness of the vegetation for producing turbulence in the air that flows over it,

the degree of resistance the leaves produce to the water movement through them, and the depth into the soil to which the roots are able to mine water.

These required properties can be estimated by mapping of the world's land surfaces into plant functional types or major biomes, overlapping approaches where biomes consist largely of single plant functional types. For example, the tropical evergreen biome consists largely of the tropical evergreen tree plant functional type. On the other hand, the savanna class biome consists of a mixture of trees and grasses. For either of these approaches or more detailed land cover classifications and for determination of albedos, global mapping requires the use of satellite imagery of the land surface. Such measurements are not as simple as determining the presence or absence of clouds but have become possible with satellite instruments developed over the last decade or two.

Canopy Processes

PD Blanken, University of Colorado at Boulder, Boulder, CO, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

This article summarizes the processes that connect vegetation canopies to the atmosphere. After a review of canopy structure and leaf arrangement, photosynthesis is discussed, including a review of the various biochemical pathways that vascular plants use to sequester carbon from and release water vapor to the atmosphere. Atmospheric controls on the connection of vascular plants to the atmosphere through stomata at both the leaf and canopy levels are discussed. Other topics discussed include light penetration through canopies, canopy productivity, wind and turbulence, and the remote sensing of canopy properties.

Introduction

The arrangement of leaves and supporting structures (branches and stems), integrated with height between the ground and the top of vegetation, forms our definition of a vegetation canopy. There is almost infinite variety in the morphology of canopies in the world's vegetation. Canopies may have several, well-defined layers, such as in rainforests, or may have one well-defined overstory, with or without a vegetated ground cover (the understory; [Figure 1](#)). A typical way to quantify the canopy is in terms of canopy closure (or gaps, where sky is visible) or the leaf area index (L ; half of the total leaf area per unit ground area, where the other half is the underside). The latter takes into account dense, multilayered canopies where L can exceed one. In general, L varies zonally across the globe, varying roughly with precipitation and temperature, and reaching a maximum near the equator and a minimum near the poles.

Superimposed on the world's spatial variability in canopy structure, there is often a great deal of temporal variability for

a given canopy. In the long term, the canopy changes through the ecological processes of succession, as a disturbance such as fire destroys the canopy and L generally increases over perhaps hundreds of years as different species colonize the area. Annually, L can vary from a maximum during the summer to a minimum during the winter as deciduous canopies seasonally lose their leaves, effectively shedding most of their canopy. On a short-term basis (hours), some species can change leaf orientation in response to water stress (e.g., soybeans), track the sun (e.g., alfalfa, cotton, and soybeans), or shed leaves in response to water stress (e.g., cotton). Even within a single species at any given time, leaf structure can vary from being thick near the top of a light-rich canopy to being thin within a shaded canopy. Oak leaves, for example, grown in the upper canopy tend to be smaller, more deeply lobed, and inclined at steeper angles than those grown beneath in the shade.

Regardless of this spatial and temporal variability, it can be argued that the motivation driving all atmospheric-related canopy processes is to achieve an optimum L that maximizes

Figure 1 Contrasting understory growth and canopy structure in a mixed hardwood deciduous forest in Michigan (left), and a subalpine coniferous forest in Colorado (right).

light absorption for photosynthesis while minimizing transpiration water loss and balancing nutrient demands with supplies. The quantity of light absorbed as it passes through a canopy drives the process of photosynthesis, which is connected to the transpiration water loss through individual leaf stomata (sing. stoma). A measure of the openness of leaf stomata at the canopy scale, canopy conductance, responds to the air temperature, humidity, wind speed (turbulence), and CO₂ concentrations, all of which to various degrees are influenced by the canopy. As a result, a canopy often creates its own microclimate.

A description of canopy processes requires integration or aggregation of processes across spatial scales ranging from the cellular to canopy scales. Such integration remains an issue, as an accurate representation of canopy processes requires the ability to 'scale up' from leaf- to canopy-level measurements, and 'scale down' back to the leaf from the canopy. In this article, canopy processes will be described for vascular plants following a scaling-up approach, covering the following topics: photosynthesis, canopy conductance, light penetration, canopy productivity, wind and turbulence, and remote sensing. The responses of plant canopy processes to changing environmental conditions such as atmospheric CO₂ concentrations, solar radiation, wind, and temperature will be discussed.

Photosynthesis

Leaf surfaces are remarkably well adapted for intercepting light. The conversion of light into carbohydrates and starches occurs through the process of photosynthesis:

Respiration is the reverse of eqn [1], with energy produced instead of required. Joseph Priestley in 1771–72 discovered that a candle would quickly extinguish when placed with a plant in a sealed chamber, yet could be relit 27 days later. Similarly, a mouse could survive in a sealed chamber only when kept with a plant. Thus, Priestley concluded that plants were somehow 'restoring' the air (oxygen had just been discovered). Subsequent experiments by others showed that only shortwave (solar) radiation between wavelengths of 400 and 700 nm (photosynthetically active radiation (PAR)), and especially between 680 and 700 nm, is absorbed by the plant for photosynthesis and required for the production of sugars and starches.

The way of CO₂ entrance into the leaf, and subsequent loss of water vapor, is through the stoma (Figure 2). Liquid water inside the leaf is required for the carbon to dissolve into the plant, and nitrogen is required to fix or sequester the carbon into a usable form. Stomata are small openings (typical length 15 μm) that are typically on the underside of leaves and are flanked by two guard cells. These guard cells regulate the aperture of the stomata by changing their turgor (internal water pressure). The plant actively regulates the stomata aperture (often expressed as stomatal conductance, or the reciprocal, stomatal resistance) by changing the guard cell turgor through changing the potassium ion concentration inside the guard cells. If, for example, the tension of water inside the water-conducting vessel in the plant (the xylem) became too great,

to prevent cavitation inside the xylem (irreparably damaging it), potassium would flow out of the guard cells. In response to the developing water potential gradient, water would flow out of the guard cells and into the adjacent epidermal cells. The turgor in the guard cells would decrease, and the stomata would close, thus reducing water loss (also carbon gain). The signal to transfer potassium in or out of the guard cells is thought to be controlled by the hormone abscisic acid (ABA), which is produced at the root hairs and carried through the xylem to the guard cells in the leaf.

Stomata provide a direct connection for gas exchange between the canopy and atmosphere, and the plant can regulate CO₂ uptake and transpiration water loss on short time scales (seconds) through changes in stomatal conductance, but also on long time scales (years) through changes in the stomatal density (number of stomata per area of leaf). The environmental clues that trigger changes in stomatal density are linked to the variables given in eqn [1], namely light quantity and atmospheric CO₂ concentrations. For example, plants grown under increased PAR levels tend to have a higher stomatal density compared to plants grown under normal PAR levels, thus taking advantage of the increased energy available to drive photosynthesis. Conversely, plants grown under elevated atmospheric CO₂ concentrations tend to have a decrease in stomatal density, and this response is also influenced by relative humidity (and therefore temperature), as one may have guessed by inspection of eqn [1]. So both the aperture of existing stomata (short term) and the development of stomata (long term) show dynamic responses to environmental clues expressed in the basic variables of the photosynthesis equation.

Biochemical Pathways

As eqn [1] shows, water is required for photosynthesis as it provides the solution in which carbon can dissolve. In addition to modifying canopy and leaf morphology to optimize light absorption, plants have evolved a number of strategies to maximize photosynthesis when water is the limiting resource. Biochemically, this includes supplementing the C₃ photosynthetic carbon reduction (PCR) cycle with the C₄ photosynthetic carbon assimilation (PCA) or crassulacean acid metabolism (CAM) pathways.

All photosynthetic eukaryotes reduce CO₂ to carbohydrates using the PCR (Calvin) cycle. In this cycle, atmospheric CO₂ and water are combined with a five-carbon acceptor molecule (ribulose 1,5-bisphosphate) to generate two molecules of a three-carbon intermediate, phosphoglycerate. This carboxylation reaction is catalyzed by the enzyme ribulose bisphosphate carboxylase oxygenase (RuBisCO), the most abundant enzyme in the world (estimated 10⁷ tons). Using the photochemically derived energy adenosine triphosphate (ATP), phosphoglycerate is then reduced to form carbohydrates (sucrose and starch). Next, the CO₂ acceptor molecule is regenerated, again using ATP. At a thermodynamic efficiency of about 90%, six turns of this cycle are required to produce the equivalent of one glucose molecule from six carbon atoms.

The enzyme RuBisCO discriminates poorly between CO₂ and O₂, and it will oxygenize ribulose 1,5-bisphosphate and release CO₂ if combined with O₂. This process, known as photorespiration (the C₂ photorespiratory carbon oxidation

Figure 2 Plan (a and c) and cross-sectional (b and d) views of an open (a and b) and closed stoma (c and d). The transfer of water vapor out of the leaf, and of CO₂ into the leaf, is regulated by the aperture of the stomatal pore; this is quantified as the leaf stomatal conductance or its reciprocal, the leaf stomatal resistance.

(PCO) cycle), is diametrically opposed to photosynthesis and results in a loss of up to 50% of the CO₂ gained by photosynthesis. To recover some of the photorespired CO₂, species found in somewhat dry and high-energy (light) tropical and subtropical climates (e.g., tropical grasses, sugarcane, corn, and sorghum) have a particularly well-developed ability to form the C₄ acids malate and/or aspartate. These acids are broken down near the site of carboxylation (the mesophyll) to regenerate an additional CO₂ acceptor molecule. Hence, C₄ species typically have high photosynthesis rates and a low stomatal conductance (high water use efficiency, as discussed further in this article), yet they require high temperatures and ample light, and are therefore seldom found in cool or shady locations such as those often found beneath a canopy.

In especially arid environments, CAM species such as cacti have the ability to reduce water loss by closing their stomata during the day and opening them at night. This high water use efficiency is achieved by obtaining CO₂ at night and fixing it in the form of the acid malate, which is stored in vacuoles. During the day, carboxylation of malate releases CO₂, which cannot escape back to the atmosphere since the stomata are closed, and is reduced to carbohydrates via the C₃ PCR cycle.

Each of these biochemical pathways for vascular plant photosynthesis is affected by atmospheric CO₂ concentrations. For example, the C₃ pathway is favored under higher atmospheric CO₂ concentrations, and the C₄ pathway is favored under lower atmospheric CO₂ concentrations. This is because there is no real advantage for a plant to spend energy to increase CO₂ concentrations in the bundle sheath cells if ambient concentrations are already high. Recently, experiments such as FACE (Free-Air CO₂ Enrichment) have been conducted to explore how contemporary increases in atmospheric CO₂ concentrations will affect these photosynthesis biochemical pathways, and therefore the distribution and abundance of terrestrial vegetation with elevated CO₂. Key findings from this 15-year study across several different canopy types included the following: trees (C₃ species) responded more than other vegetation groups (C₄ species) with an increase in carbon uptake (photosynthetic stimulation), increased *L*, an increase in dry matter production, and a decrease in stomatal conductance under elevated atmospheric CO₂ concentrations (200 ppm above current concentrations). Experiments such as FACE and other similar studies on plants and ecosystems under natural conditions show that C₃ species, especially trees, are

much more responsive to elevated CO_2 concentrations than C_4 species. Thus, we could expect long-term ecosystem shifts in composition and distribution due to changes in canopy processes caused by changing atmospheric CO_2 concentrations.

Water Use Efficiency

The success of these various processes of maximizing carbon uptake while minimizing water loss is expressed by the water use efficiency (WUE):

$$\text{WUE} = \frac{\text{moles of } \text{CO}_2 \text{ fixed}}{\text{moles of } \text{H}_2\text{O} \text{ transpired}} \quad [2]$$

This ratio captures what is often referred to as the photosynthesis–transpiration dilemma; how to maximize carbon intake while minimizing water loss. In regions where water is nonlimiting, canopies usually maximize L to maximize light interception without regard for water loss. Many freshwater wetland species, and saltwater species such as mangroves, however, do actively regulate water loss (transpiration) thorough decreasing stomatal conductance to prevalent xylem capitation in times of high atmospheric water demand (freshwater wetland species) or to prevent salt from entering the plant (mangroves; Figure 3). Ironically, these species growing in standing water show xylem water pressure potentials as low as those of desert species. In regions where water is a limiting factor (sometimes seasonally or even diurnally), various strategies in addition to the various biochemical pathways just discussed may be used to minimize transpirational water loss.

Leaf and canopy morphology are often modified to minimize water loss. New leaves and stems grown under water deficits tend to be smaller than those grown under nonstressed

conditions. Existing leaves often senesce and fall off during periods of water stress. These leaf area limitations and adjustments are usually the first responses of plants to slow, long-term dehydration. The structure of the canopy and of individual leaves (e.g., edge shapes and leaf hairs) can also affect water loss. For example, a canopy that is aerodynamically rough (e.g., forests) tends to enhance water and heat loss by having a low aerodynamic resistance (see the ‘Wind and Turbulence’ section), whereas aerodynamically smooth canopies (e.g., crops) tend to have a large aerodynamic resistance that suppresses water loss and heat exchange. Prolonged drought can also lead to an expansion of the root system into deeper soils, where water may be more plentiful than at the surface.

In response to short-term water stress, or after the plant has reached its maximum leaf area, stomatal closure can effectively reduce transpiration water loss. Stomatal closure occurs either passively when rapid water loss from the guard cells cannot be replenished by water from adjacent epidermal cells, or metabolically when solute transport from the guard cells results in water loss, decreased turgor, and hence closure. It is thought that ABA delivered to the leaf from the roots, in addition to playing a role in leaf abscission, also plays a key role in initiating stomatal closure, as it is at the roots where drying is first detected.

As discussed in this article, the quantity of CO_2 sequestered through photosynthesis depends on several factors and variables, including the ambient CO_2 concentration, quantity and quality of light (PAR), temperature and relative humidity, stomatal conductance and density (and therefore L), and biochemical pathway through which photosynthesis occurs. With elevated ambient CO_2 concentrations (and all other variables held similar), WUE generally increases (improves) for C_3 species. This is primarily due to the decrease in stomatal

Figure 3 A mangrove island remarkably well adapted to saline water in the Gulf Coast of Florida.

conductance and associated decrease in transpiration, allowing for increased soil water content and increased growth. What needs to be remembered is that other climatological changes associated with changes in atmospheric CO₂ concentrations (e.g., cloud cover hence PAR, precipitation, temperature, humidity, soils, and nutrient concentrations such as nitrogen) will almost certainly also change, hence complicating this general finding.

Canopy Conductance

The transpirational water loss from a leaf is controlled by not only processes internal to the leaf but also external processes, and considerable feedbacks occur between the two. The aggregation of leaves into a canopy alters not only the light regime but also the temperature, wind, and concentration of gases such as water vapor and CO₂. There are also concerns with scaling between the leaf and canopy, that is, does a canopy behave like a 'big leaf' so that processes observed at the leaf level can be simply multiplied to the canopy level as a function of leaf area?

An Ohm's law electrical analogy ($I = V/r$ where V is voltage, I is current, and r is resistance) has been successfully applied to describe the transfer of heat, water vapor, and CO₂ between the leaf and atmosphere, and between the canopy and atmosphere (Figure 4), and hence, it forms a basis for predicting either the leaf stomatal (g_L) or canopy (g_C) conductance. Note that conductance is the reciprocal of resistance (i.e., $g = 1/r$). Simply stated, the flux or exchange per unit area over a given time (i.e., I) is equal to the difference in concentration (potential difference) between the leaf or canopy and the atmosphere (i.e., V), divided by the resistance to this transfer (i.e., r):

$$\text{flux} = \frac{\text{potential difference}}{\text{resistance}}. \quad [3]$$

A popular approach for calculating g_C from generally available canopy-level meteorological measurements is by solving the Penman–Monteith combination equation for g_C :

$$r_C = \frac{1}{g_C} = \frac{r_a[S(R_n - G) - \lambda E(S + \gamma)] + \rho c_p D}{\gamma \lambda E}, \quad [4]$$

where r_C and r_a are the canopy and aerodynamic resistances, respectively; S is the slope of the saturation vapor pressure

Figure 4 Schematic of transfer of heat, water vapor, and CO₂ between a leaf (a) or canopy (b) and the atmosphere. At the leaf level, heat transfer depends on the difference between the leaf surface (T_S) and air temperature (T_a) divided by the leaf's boundary layer resistance (r_b), created by the transfer across the layer of still air adjacent to the leaf surface. The transfer of water vapor from the leaf is described by the difference in the saturation vapor pressure calculated at T_S ($e^*(T_S)$) and the vapor pressure at the leaf surface (e_S) divided by the leaf stomatal resistance (r_L), and the difference between e_S and the atmospheric vapor pressure (e_a) divided by r_b . Similarly, CO₂ transfer into the leaf depends on the difference in CO₂ concentration in the atmosphere (c_a) and the leaf surface (c_S) divided by r_b , and the difference between c_S and the leaf's internal CO₂ concentration (c_i) divided by r_L . At the canopy level, leaf-level values must be replaced with canopy-level values (subscript C), and r_b must be replaced with a canopy boundary layer resistance, r_{bC} . In addition, the aerodynamic resistance (r_a) between the atmospheric values and those measured at some reference height above the canopy (subscript R) must be included.

versus temperature curve; R_n is the net radiation; G and λE are the soil and latent heat fluxes, respectively; γ is the psychrometric constant; ρ is the air density; c_p is the specific heat of dry air; and D is the saturation deficit. This energy balance approach works well in an analytical sense when λE has already been measured, for example by eddy covariance (Figure 5) and when soil water evaporation is negligible. Soil water evaporation is difficult to measure, and it varies with both time and space. New measurement techniques such as stable oxygen isotopes, however, offer a promising means to partition λE into transpiration and soil water evaporation. When measurements of λE are not available, the use of eqn [4] in a predictive fashion requires that g_C be modeled, which is not an easy task given the complexity of a plant's response to the environment and vice versa.

At both the leaf and canopy levels, conductance has been found to respond to several variables, for example PAR, temperature (leaf or air), humidity (relative or the saturation deficit), and the CO_2 concentration, or $[\text{CO}_2]$ (leaf or air). The response of individual species to these or other variables varies greatly, but examples of general responses in the absence of any other environmental stresses are shown in Figure 6.

Figure 5 Eddy covariance instruments used to directly measure the fluxes of heat, water vapor, CO_2 , and momentum. A sonic anemometer measures the vertical, horizontal, and lateral wind velocity components by measuring the speed of sound between pairs of transducers. An open-path gas analyzer measures the densities of water vapor and CO_2 in a volume of air by measuring the attenuation of infrared radiation between a source and detector. The covariance between fluctuations in simultaneous high-frequency measurements of the vertical wind speed, air temperature, water vapor, CO_2 , and horizontal wind speed are used to calculate each of the fluxes.

The approach taken by researchers to develop species-specific relationships has been either to make measurements on individual leaves in a laboratory under controlled conditions, or to make measurements on individual leaves in the natural environment under either controlled conditions or a wide variety of conditions. Individual leaf measurements are obtained by placing a leaf into a cuvette (Figure 7), and then using either multiple regression (an additive model; see eqn [5], where a through d are regression coefficients, and x_1 through x_3 are the various independent variables influencing g_L) or a boundary-line analysis to determine the stomatal response to the measured environmental variables. The latter analysis involves measuring g_L under as many ambient conditions as possible (and thus requires large amounts of data), then fitting and defining curves to the upper data points (e.g., $f(x_1)$), where points below these curves represent times when g_L was limited by some other variable. The data are then standardized by the maximum observed g_L ($g_{L\max}$), to form a multiplicative model (eqn [6]). Once the relationships between g_L and the environment are quantified, scaling from leaf to canopy is then accomplished with knowledge of the leaf area index (eqn [7]). If a single-species canopy has several layers, then g_L and L should be measured for each individual layer, multiplied, and then summed. If there are several species in the canopy, then g_L and L for each species should be measured, multiplied, and then summed to scale up to the canopy.

$$g_L = a + bx_1 + cx_2 + dx_3 \dots \quad [5]$$

$$g_L = g_{L\max} [f(x_1)f(x_2)f(x_3) \dots] \quad [6]$$

$$g_C = g_L L \quad [7]$$

It has also been recognized, however, that in addition to g_L responding to relative humidity at the leaf surface (h_s), g_L in some species also responds to the $[\text{CO}_2]$ by varying g_L to maintain a constant $[\text{CO}_2]$ at the leaf surface (c_s). These two driving variables, h_s and c_s , are combined in an empirical model widely recognized as the Collatz model, which is based on the Ball-Berry-Woodrow index:

$$g_L = m \frac{A}{c_s} h_s + b, \quad [8]$$

or, at the canopy scale:

$$g_C = m \frac{A_C}{c_C} h_C + bL, \quad [9]$$

where m and b are empirically derived coefficients based on cuvette gas exchange studies, A is the net carbon assimilation rate, and the subscript C refers to canopy-level values. In eqns [8] and [9], conductance is now a function of the net assimilation rate and vice versa, hence eqns [8] or [9] must be solved iteratively using a series of equations that describes both conductance and photosynthesis.

Equation [9] still remains the common means of calculating canopy conductance in climate models, such as the Community Land Model (CLM4). While the basic form of eqn [9] remains unchanged, improvements in model accuracy have been achieved when the physiologically based parameters are changed based on improved measurements under a greater range of ambient conditions for more canopy types.

Figure 6 Examples of the response of leaf stomatal or canopy conductance to photosynthetically active radiation (a), leaf temperature (b), saturation deficit (c), and atmospheric CO₂ concentrations (d) when all other environmental stresses are absent.

Figure 7 Using a steady-state porometer to measure the leaf stomatal conductance of *Carex aquatilis* in the Hudson Bay Lowland near Churchill, Manitoba, Canada.

Light Penetration

A canopy develops because of competition for sunlight, which is required for photosynthesis and hence growth. Trees, through their intricate structure of leaves supported by stems and branches, are remarkably well adapted for light interception, and hence, they outgrow nonstemmed species. Whereas an individual leaf typically absorbs roughly 50% of the incident shortwave radiation, a canopy typically absorbs roughly 80%. The canopy's advantage stems from the absorption by leaves lower in the canopy of the scattered and reflected light created as light passes through the upper canopy.

To quantify the fraction of the top of the canopy (incident) radiation (f) that penetrates the canopy to a depth z , a version of Bouguer's or Beer's law is often used:

$$f_z = e^{-KL_T}, \quad [10]$$

where K is the extinction coefficient and L_T is the cumulative leaf area index between the top of the canopy and z . The fraction of the incident beam radiation intercepted by the canopy is $1 - f_z$. The extinction coefficient K varies with the solar zenith angle (thus K varies both diurnally and seasonally), the optical properties of the leaves, and the canopy's leaf angle distribution; thus, it can vary largely with the canopy architecture. Equation [10] can also be used to estimate the attenuation of other streams of radiation with canopy depth (e.g., net all-wave radiation or PAR) as long as the appropriate radiation-specific K is used.

When L is measured, either optically with commercially available instruments or by leaf harvesting or litter collection, eqn [10] allows for profiles of light penetration to be calculated (Figure 8). This in turn allows canopy processes

Figure 8 Example of the profiles of the leaf area index (a), the cumulative leaf area index (b), and the fraction of radiation at the top of the canopy that penetrates to a given height calculated using eqn [10] (c). The extinction coefficient K determines the rate at which the radiation is attenuated through the canopy.

that are driven by light absorption to be calculated at multiple levels within a canopy. Use of eqn [10] assumes a homogeneous canopy with randomly distributed leaves that absorb all of the radiation. Realistically, leaves are not randomly distributed in a canopy but are often grouped or ‘clumped’ together around whorls or branches. To account for this, eqn [10] can be modified by multiplying L_T by a clumping factor, Ω . Various additional modifications to eqn [10] exist to account for light scattering and reflection, multispecies canopies, and spatially heterogeneous canopies. Nonetheless, inherent in all of these modifications is the assumption that radiation decreases exponentially through the canopy as a function of the cumulative leaf area index and an extinction coefficient.

The leaf area index and the structure and arrangement of leaves are influenced by the quality of the light being received at the leaf level. Changes in not only the wavelength of the incident radiation but also the direction of that radiation (e.g., as a direct beam from the Sun or diffused after scattering) have been shown to affect the rate of photosynthesis and hence plant growth and productivity. For example, many species, especially coniferous ones with their small, cylindrically leaves and canopy structure, have higher photosynthetic rates (greater carbon uptake) and light use efficiencies under cloudy conditions when the portion of diffuse-beam PAR radiation is high, since the leaves (canopy) can absorb radiation from multiple angles due to their cylindrical shape. In contrast, broad-leaf species (e.g., most deciduous species) have higher photosynthetic rates under clear-sky conditions since their leaves are better positioned to intercept PAR radiation at lower solar zenith angles. Recent global surface and satellite-based measurements of surface solar radiation have shown periods of decreased surface solar radiation (global dimming; ~1960–90) and subsequent periods of increased surface solar radiation (global brightening; ~1990–present). These changes will affect plant productivity, for example by increasing carbon uptake during periods of increased cloud cover due to the increase in the fraction of diffuse-beam relative to direct-beam solar radiation.

Canopy Productivity

For a canopy, we define the net primary productivity (NPP) as the difference between gross primary productivity (photosynthesis, or GPP) and respiration (R):

$$\text{NPP} = \text{GPP} - \text{R}. \quad [11]$$

In other words, the carbon gained by the canopy is the difference between the amount of carbon that is gained by photosynthesis minus losses of carbon by respiration. If water and nutrients are available, eqns [1] and [11] show that the NPP of a canopy is limited only by the absorbed PAR and by respiratory carbon loss, the latter largely a function of temperature. Since NPP, or canopy growth, is a function of these two different processes, changes in the environment that affect the balance between GPP and R will affect canopy growth.

The main variables affecting GPP have already been discussed, namely, light absorption, leaf area, and canopy architecture. Other variables, including water and nutrient availability, also affect GPP. For example, the growth of most plants is limited by the relatively low atmospheric CO_2 concentration, and an increase in atmospheric CO_2 concentration would result in increased photosynthesis, biomass, and water use efficiency in many species, as discussed in this article. Recently, FACE has been investigating the effects of increasing atmospheric CO_2 concentration (370 versus $550 \mu\text{mol mol}^{-1}$) under open-air conditions on several natural ecosystems. With CO_2 enrichment, results have shown increased photosynthesis rates by up to 75%, increased canopy temperature due to reduced transpiration by partial stomata closure, and increased success and dominance of exotic, invasive species.

Any increase in GPP due to an increase in atmospheric CO_2 concentrations, however, may be limited by the availability of several other nutrients, especially nitrogen. Despite an abundance of nitrogen in the atmosphere (~78% in the homosphere), it is not in a form that plants can use due to the stable triple covalent bond between the two nitrogen atoms, which is difficult to break. Only roughly 10% of the nitrogen in a usable

form is made available to plants in precipitation by breaking of the bonds via lightning. The remaining 90% is made available through the process of biological nitrogen fixation. As relatively few plant species are themselves capable of converting or fixing nitrogen into a usable form, they rely on microorganisms to do this. The cycling of nitrogen in its various forms between the atmosphere, plants, and soil is the key to productivity in many of the world's canopies.

Especially in forests, NPP is the difference between two large numbers; respiration is just as important as or more important than GPP. Several large-scale experiments such as the Boreal Ecosystem-Atmosphere Study (BOREAS), EUROFLUX (the Long-term Dioxide and Water Vapor Fluxes of European Forests and Interactions with the Climate System project), and AmeriFlux were conducted to study the long-term carbon balance across several forests around the world. Some results show that, especially at higher latitudes, it is the ecosystem respiration that determines the net ecosystem carbon exchange, not photosynthesis. Moreover, the winter season is important for the annual NPP since R , although small, is large annually when cumulated over the longer winter season. As short-term experiments have shown that microbial respiration increases with warming, this suggests that with global warming, canopies will become less effective in removing atmospheric CO_2 since any carbon gains would be offset by the increased respiratory carbon loss. Over long periods of time (decades), however, recent studies have shown no control on respiration rates by temperature. If this were correct, global warming would result in an increase in atmospheric carbon sequestration by plant canopies, as the respiratory carbon loss would not increase.

Wind and Turbulence

The final section in our discussion of canopy processes is on the effects of wind. Wind cannot only affect the shape and size of vegetation (Figure 9) but also influence the turbulent dispersion of heat and gases such as water vapor and CO_2 . It also influences light penetration (through the movement of leaves creating sun flecks); the removal of intercepted precipitation; the transport of particulates such as pollen, spores, and pollutants; and canopy stability (wind sway or wind throw).

Air flowing over a leaf does not behave as if the leaf were a flat, smooth surface. Serrations at the edges of leaves as well as leaf ribs generate turbulence over the leaf. Turbulence serves to increase the exchange of heat, water vapor, and CO_2 , since exchange in turbulent air is much more efficient than exchange in still air. Over a canopy, air flow is reduced both by skin friction, or the transfer of momentum across the horizontal canopy boundary layer, and by form drag, or the force exerted when air strikes the canopy in a direction other than horizontal. The combination of these two forces is expressed by the total shearing stress, τ :

$$\tau = K_M \rho \frac{du}{dz}, \quad [12]$$

where K_M is the eddy viscosity, and du/dz is the change in horizontal wind speed u with height z . Since leaves and canopies are flexible, τ changes with wind speed as the canopy changes form, often becoming more streamlined as u increases.

Figure 9 Effects of persistent high wind speeds on the shape and structure of alpine vegetation in Colorado. A common alpine vegetation feature known as a krumholtz forms with a dense mat of branches near the ground, with a few stems with branches prevalent on the leeward side.

Wind can also affect photosynthesis, especially in understory species and leaves. A thick, multilayered canopy can effectively reduce u within the canopy, sometimes resulting in leaf temperatures and relative humidity increasing, which, as shown in eqn [8], acts to increase leaf stomatal conductance. Sun flecks, patches of full sunlight that pass through gaps in the canopy, can increase in frequency, duration, and size as wind moves the canopy. Exposure to sun flecks has been found to lower the photosynthetic rate in light-intolerant understory species or increase the photosynthetic rate in shade-tolerant understory species.

Canopies can influence the wind around them, in addition to being affected by the wind itself. Depending on the canopy properties (height, density, and leaf area index), extensive canopies alter the wind profile by creating a layer known as the roughness boundary layer, a layer of turbulent flow at the top of the canopy that influences the exchange of heat and mass (carbon and water vapor) from the vegetation. Within many forests, higher wind speeds are observed within the trunk space due to decreased canopy structure (fewer leaves and branches) and topography-driven cold-air drainage flows. In boreal or alpine regions, vegetation often promotes the retention of the beneath-canopy snowpack due to the canopy's shading of the snowpack, providing the benefit of insulating the soil (roots) from subzero temperatures and temperature fluctuations, and providing soil moisture during spring snow melt. In the lee of canopies and even isolated vegetation patches such as alpine krumholtz, the decrease in wind speed is often sufficient to deposit wind-blown snow and create snowdrifts (Figure 10). If properly designed,

vegetation can be used to create effective and economical living snow fences.

Precipitation Interception

Canopies are effective at intercepting precipitation. Water external to the leaf is free from direct physiological controls, thus it is either evaporated (rainfall) or sublimated (snowfall); both processes are influenced by wind. Depending on the canopy leaf area and architecture, roughly 10–55% of the total annual precipitation can be intercepted and subsequently lost through evaporation. Generally, the ability to intercept precipitation increases with leaf area, and the ability to evaporate this precipitation also increases due to a decrease in the aerodynamic resistance with increasing leaf area. Increasing wind speed increases the evaporation rate of intercepted rainfall by decreasing the aerodynamic resistance or by mechanically shedding water from leaves, resulting in throughfall. Especially in coastal and mountainous environments, leaves can act as condensation nuclei as fog collides and coalesces on individual leaves.

Similarly, as the canopy's L increases, the potential to intercept snow increases, and therefore, the snow water equivalent at the forest floor decreases. Sublimation losses of intercepted snow are especially significant in boreal coniferous stands (e.g., up to 40% of the annual precipitation) where the leaves are present during the long winter snowfall season. The bridging of snow across leaves and branches can effectively increase the interception area, and strong winds can effectively remove large volumes of snow off the canopy.

Figure 10 An example of vegetation's ability to alter its microclimate. Just above the alpine tree line in Colorado, the decrease in wind speed behind the vegetation created a snowdrift that insulated leaf tissue and roots from temperature extremes and provides valuable soil moisture.

Particulate Transport

The transportation of particulates such as pollen, spores, and pollutants is affected by wind, especially within the canopy where origination or deposition of many particulates occurs. Wind decreases exponentially with height within most canopies, with an attenuation or extinction coefficient generally a function of the cumulative L . In canopies with a dense overstory and open space beneath, however, the wind speed and direction can be unrelated to that above the canopy due to within-canopy horizontal pressure differences. In such canopies, a secondary maxima in u is often observed within the stem space.

In canopies, both the take-off and dispersion or flight of particles must be considered. To dislodge a particle from a surface, the drag force (a function of u) and lift force produce a turning moment (created by a difference in static pressure between the top and bottom of the particle) that must exceed the turning moment due to the force of gravity. Hence, a threshold u at the particle level is required to entrain the particle into the atmosphere, yet the u at this level is usually very low with nonturbulent flow. Therefore, many species have developed active methods to project or assist the entrainment of particles into the moving air stream.

Once the particle is in the air stream, its path is usually chaotic and random, and it has been successfully described for small particulates by diffusion theory borrowed from air pollution studies, Lagrangian simulations of particle trajectories, or, more recently, large-eddy simulations. The particle will land when the forces of gravity and drag exceed the lift force.

Structural Failure

The structural failure of canopies is of great economical significance for agricultural canopies, whether crops or forests. The shaking of plants as a result of wind has been proven to inhibit plant growth, as has the exposure of plants to particulates such as ice crystals or sand. The force required to catastrophically overturn a plant can be calculated from the forces acting on the plant, where the lateral force required to exceed the turning moment is a function of u and the drag coefficient for the canopy. The average threshold u required for catastrophic plant structural failure, however, fails to predict when stem failure will occur because canopies behave as aeroelastic structures. Such structures fail when the gust frequency, with mean wind speeds that may be below the theoretically required threshold average wind speed, coincides with the natural oscillation frequency of the canopy. Additional factors such as soil texture, structure, and moisture should also be considered, as mechanical failure of the soil could occur if, for example, the soil became saturated.

Remote Sensing of Canopy Properties

Given the sparseness of ground-based point measurements of canopy processes, and the need for large-scale and long-term observations, there have been many recent developments in the use of satellite observations to quantify the biophysical properties of plant canopies. For example, data from the NOAA Advanced Very High Resolution Radiometer

(AVHRR) can be used to calculate several biophysical properties at a resolution of 1.1×1.1 km. Of the several remote-sensing vegetation indices that exist, one using AVHRR data is the Normalized Difference Vegetation Index (NDVI):

$$\text{NDVI} = \frac{(\rho_{\text{NIR}} - \rho_{\text{RED}})}{(\rho_{\text{NIR}} + \rho_{\text{RED}})}, \quad [13]$$

where ρ_{NIR} ($0.7\text{--}1.1\ \mu\text{m}$) and ρ_{RED} ($0.6\text{--}0.7\ \mu\text{m}$) are the reflectances in the near-infrared and red wave bands, respectively, and can be used to estimate L and the fraction of PAR absorbed by a canopy (FPAR). Complementary to NDVI, the Moderate Resolution Imaging Spectroradiometer (MODIS) can be used to calculate the Enhanced Vegetation Index (EVI), which has greater sensitivity to canopy structure:

$$\text{EVI} = \frac{2.5(\rho_{\text{NIR}} - \rho_{\text{RED}})}{(L_C + \rho_{\text{NIR}} + C_1\rho_{\text{RED}} - C_2\rho_{\text{BLUE}})}, \quad [14]$$

where L_C (typically 1) is the canopy background adjustment factor, C_1 and C_2 are aerosol resistance weights (typically 6 and 7.5, respectively), and ρ_{BLUE} is the reflectance in the blue wave band ($0.45\text{--}0.52\ \mu\text{m}$). Hyperspectral remote-sensing instruments (capable of resolving hundreds of spectral bands), such as the Airborne Visible/Infrared Imaging Spectrometer (AVIRIS) and Hyperion, can be used to not only identify vegetation cover but also identify the vegetation type (species). Various passive microwave sensors and radar can be used to detect changes in soil moisture, especially in agricultural crops when the canopy cover is still sparse. New satellite-based measurements such as those provided by the Gravity Recovery and Climate Experiment (GRACE) have been used to help estimate canopy processes such as evapotranspiration in combination with measured precipitation and runoff measurements.

Whereas L and FPAR can be used as measures of the capacity of the canopy to intercept PAR, the actual photosynthetic rate can be determined from the absorbed PAR (APAR). This can be derived from knowledge of APAR below the top of the canopy (APAR_{SFC}), the amount of PAR reflected from the top of the canopy (A_{PAR}), and FPAR:

$$\text{APAR} = \frac{\text{APAR}_{\text{SFC}}}{1 - A_{\text{PAR}}} \text{FPAR}. \quad [15]$$

The ability to remotely sense APAR is important as APAR inherently drives all of the canopy processes discussed in this article.

Despite this tremendous potential for remotely sensing these canopy properties, complex algorithms are required to correct for atmospheric effects such as clouds, aerosol and ozone absorption, sun angle, and bidirectional reflectance. Thus, ground-based point measurements are still required to ensure that the remotely sensed canopy properties are indeed accurate.

Trace Gas Exchange

JN Cape and D Fowler, Edinburgh Research Station, Midlothian, UK

Synopsis

The theory and background to the exchange of trace gases at the Earth's surface are presented as an introduction to the experimental methods used for measuring trace gas exchange, and the roles of weather and surface vegetation in controlling the process. Measurement systems over a range of spatial scales, including small chambers, micrometeorological techniques, and aircraft studies, are described, and the use of measurement data in deposition models is briefly introduced.

Introduction

The exchange of trace gases between the Earth's surface and the atmosphere is a fundamental process of life. Primary productivity, as photosynthesis, involves uptake of carbon dioxide and release of oxygen and water vapor. Many trace gases are also involved in biogeochemical cycling of nutrient elements, in particular, sulfur and nitrogen. Gases such as sulfur dioxide (SO_2), hydrogen sulfide (H_2S), carbonyl sulfide (COS), dimethylsulfide ($(\text{CH}_3)_2\text{S}$), nitrous oxide (N_2O), nitric oxide (NO), nitrogen dioxide (NO_2), and ammonia (NH_3) are emitted from and absorbed at the Earth's surface, by plants or soil, as part of natural processes. Industrialization has led to large artificial emissions, especially from combustion sources, of many of these trace gases, which are then returned to vegetation, soil, and water surfaces with important implications for effects including acidification and eutrophication. It has therefore become important to be able to estimate the exchange of trace gases between the surface and the atmosphere. The deposition of pollutant gases to vegetation and soils (*dry deposition*) contributes to the nutrient budgets of ecosystems, and may exceed thresholds above which irreversible changes occur. Direct gaseous deposition forms part of 'Critical Load' calculations, which are used in Europe as a means of setting strategies for pollution control. Trace gas exchange is also measured to assess responses to land-use change and pollutant stress. For example, increased deposition of N (either as fertilizer, or as atmospherically deposited pollution) can increase soil emissions of nitrous oxide (N_2O), which is an important 'greenhouse' gas. Methods of measuring trace gas exchange have also been developed to investigate the natural biogenic emissions of other radiatively active gases, such as methane (CH_4), so that forecasts can be made of the effects of changing land use or climate on uptake by, and emission from, soils. Vegetation also emits a wide range of gases, including volatile organic compounds (VOCs), which contribute to the formation of tropospheric ozone (O_3). Knowledge of biogenic VOC emission rates, and the factors that control them, is necessary for modeling the production of ozone on regional and global scales. Deposition at the ground, and uptake by vegetation, is one of the major sinks for tropospheric ozone, so this process also must be understood before atmospheric chemistry and transport models can be developed.

Transfer Processes

The transfer of gases between the Earth's surface and the atmosphere can occur in both directions, and is controlled both by atmospheric processes and by the state of the ground surface. Sources and sinks of trace gases at the ground may be in the soil itself, or both in and on the vegetation. The magnitude of the trace gas flux depends on both the physical and physiological state of the vegetation – that is, is controlled by the structure of the vegetation as it affects air turbulence, and by the biological and chemical processes occurring inside and on the surface of leaves.

Some of the trace gases, such as ammonia and nitric oxide, are deposited on and emitted from natural surfaces and the exchange is therefore bidirectional, as is the case for water vapor and carbon dioxide. Other trace gas fluxes are unidirectional, for example, the very reactive gases nitric acid and hydrogen chloride. Fluxes of trace gases to or from the surface are usually expressed as mass fluxes per unit ground area (μg or $\text{ng m}^{-2} \text{s}^{-1}$). These are often referenced to an air concentration (for downward fluxes) at a fixed height above the ground, expressed as a mass per unit volume ($\mu\text{g m}^{-3}$), in part to normalize the flux for the ambient concentration. The ratio of flux to concentration in these units is called the deposition velocity (v_d), because it has units of velocity (m s^{-1}).

Since the late 1970s, methods for measuring trace gas concentrations over short time periods (several minutes or less) have been developed, which have permitted trace gas fluxes to be measured over a range of different land surfaces by measuring vertical concentration gradients. More recently, the development of rapid response gas sensors, which can provide precise concentration measurements at frequencies of tens of Hertz, has permitted the direct measurement of trace gas fluxes using eddy covariance methods. Both of these techniques integrate over a 'footprint' of land surface upwind of a fixed measurement point, and several conditions must be satisfied for the micrometeorological theory used to determine fluxes to be valid. For example, the terrain should be uniform, and there should be very small horizontal gradients in concentration, or small changes in concentration with time, to avoid advection and storage errors in the measured flux. On a smaller scale (typically of the order of $0.1\text{--}10 \text{ m}^2$), trace gas fluxes can be measured using boxes placed on the ground, in which changes in trace gas concentrations are measured either statically or

dynamically. On a larger scale, trace gas fluxes have been calculated on scales of around 10^2 km^2 by measuring changes in trace gas concentration with time below a well-defined inversion layer when vertical mixing is suppressed. At much larger scales, fluxes have been inferred from measurements in the well-mixed boundary layer upwind and downwind of a region typically 10^4 km^2 in area.

Pathways of Gas Transfer

The transfer of gases between the atmosphere and the surface, whether bare soil or vegetation, may be thought of in terms of three consecutive pathways. Each of these pathways imposes a resistance on the overall transfer process, and the network of resistances is a convenient way of describing the different contributions of the pathways to the overall process, by analogy with an electrical circuit (Figure 1). In this model, resistance has units of time per unit length (s m^{-1}); the reciprocal (units: m s^{-1}) is referred to as a conductance. The flux is then driven by the difference in trace gas concentration between a reference height (z) in the atmosphere and the concentration at the sink (or source) at the surface, analogous to a potential difference applied across the combined resistances of the transfer pathways.

The first pathway is the transfer of gases by turbulence within the atmosphere, and depends upon the surface roughness and wind speed. The associated aerodynamic resistance (r_a) decreases with increasing wind speed, and is small for rough vegetation (e.g., forests; typically $2\text{--}10 \text{ s m}^{-1}$) and larger for short vegetation (e.g., short grass; typically $30\text{--}300 \text{ s m}^{-1}$). It is implicitly a function of height above the canopy (z), and is

generally calculated between a reference height ($z - d$) and the notional height ($z_0 + d$), where d is the displacement height associated with aerodynamically rough plant canopies, and z_0 is the roughness length of the surface. The second part of the transfer process involves the molecular diffusion of gases across the laminar boundary layer that forms at surfaces. The thickness of this layer is a function of the geometry of the leaf or surface element, and also depends on the wind speed. Although several formulations of this term (r_b) exist, it is generally small relative to the third, or surface resistance (r_c), which for most of the trace gases is the controlling step in the transfer pathway. When considering the flux of gases to or from a vegetation canopy, the surface resistance term includes several parallel pathways that depend upon the characteristics of the ultimate absorbing (or emitting) surface. Different sinks (and sources) are present in a canopy, and the surface resistance is often split into a stomatal term and a nonstomatal term. The nonstomatal term may be further decomposed into parallel pathways to understorey vegetation or bare soil, dry canopy surfaces (e.g., leaf cuticles), and wet surfaces. These parallel resistances are shown in Figure 1. Biological or chemical processes occurring at the surface control the magnitude of the surface resistance. Stomatal resistance increases as stomata close, either at night or in response to a large vapor pressure deficit. Stomatal resistance to trace gas transfer can be estimated from measurements of water vapor exchange through stomata, making allowance for the relative diffusion rates of the trace gas molecules. Alternatively, stomatal resistance may be modeled based on parameterizations of stomatal opening and closure based on light intensity and vapor pressure deficit. The nonstomatal terms are difficult to model, particularly where the gas exchange process at the surface depends upon solubility or

Figure 1 Schematic diagram showing the transfer pathways for a gas between the atmosphere and the Earth's surface, and the associated transfer resistances, which determine the overall transfer rate or deposition velocity. The deposition velocity is referenced to a height (z) above the ground.

reaction in water. The nonstomatal resistance is often obtained as the residual between the (measured) surface resistance and an estimated or modeled stomatal resistance.

Micrometeorological Theory and Methods

Measurements of trace gas exchange to the land surface over distances of 10–1000 m may be made by three techniques, which operate on different timescales. The particular method employed may be determined by the availability of an appropriate sensor for measuring the trace gas concentration and the characteristics of the surface over which measurements are to be made.

The Aerodynamic Gradient Method

The transport of gases to and from the surface is regarded as occurring by the same turbulent processes that transport momentum and heat. The flux is then determined from measurements of the vertical gradient above the surface of wind speed, temperature, and gas concentration. Formally, the flux of trace gas s (F_s) is proportional to the vertical concentration gradient: $F_s = -\rho K_s \partial s / \partial z$, where K_s is the transfer coefficient (eddy diffusivity) for gas s , ρ is the air density, and $\partial s / \partial z$ is the vertical gradient in concentration (expressed as a mixing ratio in dry air). By convention, fluxes toward the surface ($\partial s / \partial z < 0$) have a negative sign. Similarly, the flux for momentum may be defined in terms of the vertical gradient in wind speed, and the flux for heat in terms of the vertical gradient in potential temperature, with transfer coefficients K_m and K_h , respectively. The transfer coefficients are functions of the measurement height (z). In atmospheric conditions of neutral stability, the eddy diffusivities for heat, momentum, and trace gases are equal, so that the trace gas flux may be calculated from measurements of the momentum flux obtained from the vertical gradients of wind speed. This technique can use relatively slow analytical methods for measuring concentration gradients, on the assumption that atmospheric turbulence is relatively constant over periods up to about 30 min, but requires a capability to measure concentration differences with height of a few percent of the mean. In stable or unstable conditions, corrections must be applied to correct for differences between eddy diffusivities for heat and momentum transfer. Semiempirical relationships have been developed based on the measured gradients in wind speed and potential temperature, which permit the estimation of trace gas fluxes under a wide range of conditions. The development of conditional time-averaged gradient (CoTAG) methods, in which average vertical gradients are measured over long periods but only in conditions of neutral stability (by turning on and off the gas sampling pumps), has meant that average fluxes can be measured over different vegetation types on a weekly or monthly basis, and these average fluxes provide parameters for use in deposition models.

The Eddy Covariance Method

Trace gases are transported to and from the surface in turbulent eddies of air. The method can be envisaged as estimating the net flux of a gas by the simultaneous measurement of the air

concentration and vertical wind speed in different upward and downward moving eddies as they move through a hypothetical plane above the surface. Formally, the flux (F_s) is given by the mean (denoted by a horizontal bar) of the product of vertical wind speed (w) and air concentration (χ_s):

$$F_s = \overline{w \cdot \chi_s} = \overline{w} \cdot \overline{\chi_s} + \overline{w' \cdot \chi_s'}$$

where w and χ_s are the mean vertical wind speed and air concentration, and w' and χ_s' are the instantaneous deviations from the means. In order to capture the full spectrum of eddy sizes responsible for trace gas transport, the wind speeds and air concentrations must be measured at a frequency of 5–20 Hz, depending on the scale of surface roughness and the height of the reference plane above the surface. The analytical method must also be able to resolve small differences in gas concentration at that frequency. Care must be taken to ensure that sensible and latent heat fluxes, which cause vertical gradients in air density, do not introduce large uncertainties into the measurements. This method is able to resolve rapid changes in surface characteristics, and is applicable for use in aircraft, where the horizontal resolution is determined by the frequency of measurements.

There have been many variants of the eddy covariance technique, mainly to overcome the limitations in the ability of the available instrumentation to sample the trace gas concentration at a sufficiently high frequency. A technique known as disjunct eddy covariance takes a series of spot samples of air at discrete intervals and collects the high frequency turbulence data for each of the air samples. In this way the air samples may be analyzed for their composition (e.g., for VOCs), and the flux calculated from the statistics of the sampling regime.

The Eddy Accumulation Method

This is a variant of the eddy covariance method, but does not require rapid gas analysis. Instead, the air sampling system is controlled by the vertical wind speed sensor (usually a sonic anemometer) to direct the sample air stream through one of three sample inlet lines, where gas can be accumulated (in a bag, or trapped on an absorbent material) prior to analysis. The three inlet lines correspond to upward moving eddies, downward moving eddies, and slack air. Very rapid (>1 Hz) valve switching is required, and the sampling rate should be proportional to the measured vertical wind speed. In practice, this latter requirement is technically difficult to achieve, and the method of relaxed eddy accumulation is more often employed. In this case, the sampling rate remains constant, and the vertical flux is estimated as the product of the standard deviation of vertical wind speed, the difference in average concentration in upward and downward moving eddies, and a scaling factor that depends on the nature of the surface. The scaling factor is determined by reference to the flux of water vapor obtained by eddy covariance or gradient methods, or may be estimated empirically for a given surface.

Constraints and Uncertainties in Measurements

The above methods are based on the assumption that the flux to or from the surface is sufficiently close to the value measured at some reference height above the surface that

simple corrections may be applied to derive the actual surface flux. In practice, several processes may upset this 'constant flux' assumption:

1. Chemical reaction between the measurement height and the ground

Trace gas concentrations may be depleted or enhanced below the measurement height, so that there are additional sinks/sources besides transfer at the surface. Examples include the loss of ozone (O_3) by reaction with nitric oxide (NO), which may have originated from microbial processes in the soil, the production of nitrogen dioxide (NO_2) from the same reaction, or the reaction of terpenes and other biogenic hydrocarbons with O_3 and hydroxyl (OH) radicals. The uncertainty is greatest for fast chemical reactions that occur on timescales similar to the transport processes. In such cases, actual surface fluxes can usually only be calculated by independent measurement of all the factors influencing the reaction rates, and detailed modeling of the coupled transport/chemistry system. Simplifications can be introduced if constraints on the system can be measured independently (e.g., in the case of $NO + O_3$, by measuring the NO flux from the soil surface directly).

2. Changes in mean concentration with time

Changes in air concentration with time lead to 'storage' errors, where a component of the vertical transport relates to the restoration of equilibrium across the reference plane as concentrations above or below change through factors not related to the surface processes. Large uncertainties can arise when there are marked changes in mixing layer height, for example, just after sunrise.

3. Horizontal gradients in concentration

Uncertainties are caused by advection of air horizontally below the measurement height when there are horizontal gradients in air concentration, and may be important for major pollutant gases close to sources. For example, an error of around 40% is introduced for a reference height of 1 m by a horizontal gradient of $10 \mu\text{g m}^{-3} \text{ km}^{-1}$ where the vertical flux is $50 \text{ ng m}^{-2} \text{ s}^{-1}$. Such gradients may be found close to urban areas or large point sources, in regions where flux measurements may be important in determining the rates of pollutant deposition and their effects.

Large-Scale Measurements

The Nocturnal Box Method

When a stable temperature inversion forms close to the Earth's surface, the air closest to the ground is effectively isolated from the atmosphere above. Provided that the boundary layer is well mixed, the emission or deposition of gases at the surface results in a gradual increase or decrease in concentration under the inversion. If the depth of the surface layer is known, or can be estimated, the change in concentration with time can be used to infer the rate of exchange of a gas at the surface. Where conditions are stable for several hours, the change in concentration measured at a fixed point follows a first-order increase or decrease from which the flux may be calculated directly. Such measurements integrate over a large surface area. This

method is not applicable to gases where chemical production or loss in the surface air would cause temporal changes in concentration, but has been used to estimate rates of O_3 deposition in rural air (where reaction with NO is negligible), and the deposition of the nonreactive gases CO and H_2 .

The Daytime Boundary Layer Budget Method

In a well-mixed daytime boundary layer with a well-defined capping inversion, and in the absence of deep convection, concentration measurements made within the boundary layer can be taken as representative of the whole mixing depth, typically of the order of 1 km. If there is a steady horizontal wind over a period of hours then air can be sampled (from an aircraft) along a transect upwind of a region, and subsequently measured along a transect downwind of the region. In this context a region can be several hundred kilometers across. The flux to or from the surface is then calculated from a mass balance of gas entering and leaving the hypothetical box formed by the capped boundary layer. In practice, this method is only applicable to gases that react very slowly in the atmosphere, but has been applied to the estimation of total fluxes of methane (CH_4) and nitrous oxide (N_2O) from the United Kingdom.

Small-Scale Measurement Methods

Gas exchange fluxes can be measured on spatial scales of $0.1\text{--}10 \text{ m}^2$ using enclosure methods. At small spatial scales there are problems with surface heterogeneity, and such techniques are often used to elucidate functional relationships between fluxes and environmental conditions such as temperature or surface wetness, while recognizing that the absolute fluxes measured may vary greatly over distances of $10\text{--}100 \text{ m}$.

Static Boxes

This technique is well suited to unreactive gases such as CH_4 and N_2O , where interactions with the box materials are not important. The rate of change of gas concentration within a box sealed to the surface is measured with time, and the flux determined from the volume–surface area ratio and the rate of change in concentration. The method is well suited to sampling fluxes across wide-ranging conditions of soil and short vegetation, but using such data to estimate field-scale fluxes generates large uncertainties unless the surface is homogeneous. The environment inside the closed box will in general be very different from that outside, with turbulent mixing greatly suppressed (unless an internal fan is used), and large changes in concentrations of water vapor and carbon dioxide if vegetation is enclosed.

Dynamic Boxes

As in the static box method, a box is sealed to the surface, and the gas concentration is measured in air pumped into and out of the enclosed volume. The surface flux is then calculated from the volume–surface area ratio, the airflow rate through the box, and the difference between inlet and outlet concentrations.

Although still subject to the same problems of sampling the underlying surface as for static boxes, the finite residence time means that fluxes of chemically reactive gases can be measured in this way, particularly if the box is constructed of chemically inert materials. However, such methods inevitably alter the conditions above the surface, if only because the surface is isolated from atmospheric turbulence. Internal mixing fans may be used to provide turbulence, but in general these will not reproduce the air movements in the absence of the box. This does not invalidate the use of such methods for process-based studies, but introduces unquantified uncertainties into the measured fluxes and their relationship to the actual surface flux outside the box.

Control of Trace Gas Fluxes by Surface Processes

Stomatal vs Nonstomatal Pathways

The transfer resistance between the atmosphere and the surface has been described in terms of atmospheric factors, which control r_a and r_b , and surface factors, r_c . In the simplest case, with highly reactive gases such as nitric acid vapor (HNO_3) or hydrogen chloride (HCl), the surface resistance term is small relative to the atmospheric transfer resistances. Under these conditions, trace gases are deposited to vegetation at rates approaching those for momentum, with deposition velocities up to several centimeters per second, depending on wind speed and surface roughness. At the other extreme, the nonstomatal surface resistance is very large, so that transfer of the gas only occurs when stomata are open. This type of behavior is observed for nitrogen dioxide (NO_2). More generally, emission or deposition occurs through both stomatal and nonstomatal pathways, with total surface resistances varying diurnally and seasonally. Although the contribution of the stomatal pathway can be estimated fairly precisely from simultaneous measurements of water vapor fluxes, elucidation of the nonstomatal pathways is more difficult. The nonstomatal resistance at the surface is usually obtained by difference between the momentum flux above a vegetation canopy ($r_c = 0$), the overall gas flux and the estimated or measured stomatal flux. The residual nonstomatal flux comprises several different potential sink or source processes, as illustrated in Figure 1. For example, although deposition of O_3 follows a diurnal cycle that coincides with stomatal opening, the nighttime flux (when stomata are closed) can be a large fraction of the daytime flux. Integrated over a whole year, the nonstomatal flux may even be greater than the flux to the inside of the leaf. However, the precise mechanisms regulating reactions on cuticular surfaces remain uncertain. The focus of interest in O_3 deposition is on the stomatal term, which leads to physiological damage to mesophyll tissue. For emission, similar patterns may be observed, with emissions from vegetation of some VOCs following stomatal opening, while emissions of other VOCs appear to be relatively invariant through day and night, and more responsive to temperature.

Chemical Reactions at the Surface

Additional complications arise for gases that dissolve in, or react with, surface water. Water-soluble gases such as sulfur

dioxide (SO_2) are rapidly absorbed through stomata, and if external leaf surfaces are dry the flux is determined by stomatal opening. However, in the presence of surface moisture, a parallel transfer pathway becomes possible, and the overall flux may be dominated by nonstomatal deposition. The surface moisture is not an infinite sink for SO_2 , and in practice the surface flux will be determined by factors such as the acidity of the surface water and the rate of oxidation to sulfate. A dynamic equilibrium may be established between the atmosphere and the solution of the trace gas on the surface, so that the net flux approaches zero. If the surface water subsequently evaporates, dissolved SO_2 may be released back into the atmosphere, producing an upward flux. If sufficient ammonia (NH_3) is also present, rapid uptake of this highly soluble gas into the surface water maintains the conditions of low acidity that favor SO_2 uptake, and the surface resistance can approach zero. More generally, a detailed understanding of all the chemical processes, including surface ion exchange and oxidation pathways, is needed before the overall transfer of SO_2 can be successfully modeled.

Bidirectional Exchange

The surface exchange of NH_3 is possibly the most complex of all the trace gases. The internal intercellular fluids of leaves contain ammonium ions, which are in dynamic equilibrium with gaseous NH_3 . The overall direction of the surface exchange therefore depends upon the relative concentrations of the gas inside and outside the leaf. If the surface exchange were purely stomatal, then the process could be relatively simply modeled from knowledge of the internal ammonium concentration and the air concentration of the gas. However, NH_3 also interacts with external leaf surfaces, which can provide a sink for both atmospheric NH_3 and NH_3 emitted from stomata when air concentrations are very small. Moreover, the difference between internal and external NH_3 concentrations may vary through a plant canopy, so that NH_3 emitted close to the ground is reabsorbed before it can escape from the vegetation canopy. In this situation even the simple resistance model of Figure 2 is not appropriate, and terms equivalent to capacitors in the electrical analog must be introduced. Much progress has been made in recent years, however, and measured hourly fluxes (both upward and downward) have been successfully modeled over periods of days for several vegetation types.

Bidirectional trace gas fluxes are not restricted to NH_3 . Microbial processes in soil can switch from consumption to production of trace gases as soil water status changes. Depending on soil type, anaerobic conditions lead to emission of N_2O , CO , and CH_4 , while in drier soils CO and CH_4 are consumed, and NO is released rather than N_2O . The switch from one type of behavior to the other can be seen in the same soil, as the soil water status changes. At the field scale, local differences in soil chemistry and structure can mean that some patches are emitting a gas which is being absorbed only a few meters away. Perhaps the best illustration of this type of behavior is in blanket peat bogs, where CH_4 is consistently emitted from wet pools and removed (by oxidation) at neighboring drier tussocks. At the scale of the landscape, the net flux is determined by the relative proportion of wet and dry areas.

Figure 2 Schematic representation of bidirectional exchange using a resistance analogy (cf Figure 1). This formulation permits both upward and downward fluxes to be modeled by comparing the gas concentration above the surface (χ_a) with the canopy compensation point concentration (χ_c). Modeling the surface-atmosphere exchange of ammonia. *Atmospheric Environment* 44 (7), 945–957.

Model Parameterization for Mapping Trace Gas Fluxes

One of the main objectives of measuring trace gas exchange is to be able to quantify fluxes at the regional, national, or global scale. The complexity of the processes involved, for all but a few gases, means that simplifications must be introduced into models designed to estimate large-scale fluxes and budgets. Initially, the modeling of surface exchange as part of schemes to represent long-range transport and fate of trace gases used single parameters for the deposition velocity of each gas. More complex models might vary the deposition velocity by night and day. As understanding improved, models were modified to calculate explicitly the atmospheric resistance terms, as a function of mean wind speeds and vegetation type, using climatological maps of wind speed and vegetation classifications based on survey or remote sensing. The most recent models include factors to account for surface wetness, and may model stomatal opening from parameterizations based on a range of different vegetation types and responses, with explicit dependence on temperature and light levels. The introduction of detailed surface chemical processes (e.g., the dependence of SO_2 deposition rates on the availability of NH_3) is still beyond the scope of regional and national modeling, not least because the required data on air

concentrations are not available at the spatial scales necessary. The evaluation of the uncertainties in such models, arising from the inevitable use of spatially and temporally averaged data (for meteorological as well as chemical parameters) is an active area of current research.

Synopsis

Light detection and ranging (Lidar) is a remote sensing technique that is used for measuring atmosphere parameters, such as temperature, composition, and wind. Lidar, like radar, operates by transmitting a beam of electromagnetic radiation and subsequently detecting any radiation scattered back to the instrument. The scattered radiation is analyzed in order to determine some property, or properties of the medium through which the radiation traveled. The range of atmospheric parameters that can be measured with lidar include: temperature, wind velocity, atomic and molecular species concentration, and aerosol and cloud properties.

Introduction

Light detection and ranging (Lidar) is a remote sensing technique that is used predominately for measuring atmosphere parameters, such as temperature, composition, and wind. Lidar operates on the same principle as radar; in fact, it is sometimes called laser radar. Both these techniques operate by transmitting a beam of electromagnetic radiation and subsequently detecting any radiation scattered back to the instrument. The scattered radiation is analyzed in order to determine some property, or properties of the medium through which the radiation traveled. Lidar and radar differ in the wavelength of the radiation utilized. Radar uses wavelengths longer than about 1 cm, in the radio-band, while lidar uses light in the ultraviolet, visible, and infrared, which in modern lidar systems, is generated by lasers. The different wavelengths used by radar and lidar leads to the very different forms the actual instruments take.

The range of atmospheric parameters that can be measured with lidar include: temperature, wind velocity, atomic and molecular species concentration, and aerosol and cloud properties.

In addition to its atmospheric applications, lidar is also used in ocean research and military applications including the

detection of chemical and biological agent and remote identification and tracking of vehicles. Lidar equipped binoculars are used by hunters and golfers as they provide accurate range measurements.

Evolution

The principle of lidar was first proposed in 1930. The original proposal suggested the measurement of atmospheric density profiles by the detection of scattering from a beam of light projected into the atmosphere. This proposed scheme suggested an antiaircraft searchlight as the source of the beam and a distant large telescope for the receiver. In this configuration, now known as bistatic, the range of the scattering can be determined by geometry. In the bistatic configuration, shown in [Figure 1](#), the receiver field of view is scanned along the transmitted beam in order to obtain an altitude profile of the scattered light.

The first results obtained using this principle were reported in the late 1930s when photographic recordings of light scattered from a searchlight beam were made.

Typically, modern lidar systems are monostatic in configuration with the transmitter and receiver colocated. Monostatic

Figure 1 Three possible alignment arrangement of a lidar's transmitted beam and receiver field of view.

Figure 2 Schematic illustrating the process of ranging based on timing the returned signal.

systems can be subdivided into two categories; coaxial systems where the laser beam is transmitted coaxially with the receiver's field of view, and biaxial systems, where the transmitter and receiver are located adjacent to each other. Monostatic lidar systems use pulsed light sources, thereby enabling the range at which scattering occurs to be determined from the round trip time of the scattered light (**Figure 2**).

By the early 1950s refinements in technique and improved instrumentation, including electrical recording of the intensity of the backscattered light, allowed the measurement of atmospheric density profiles up to around 67 km altitude. These measured density profiles were then used to derive temperature

profiles using the Rayleigh lidar technique, which is described later.

The invention of the laser in 1960 and the giant pulse, or Q-switched, laser in 1962 provided a powerful new light source for lidar. The first use of a laser in a lidar system was reported in the early 1960s and since then developments in lidar have been closely linked to advances in laser technology.

Instrument Basics

Lidar hardware can be conveniently divided into three subsystems: the transmitter, the receiver, and the detection and recording systems. **Figure 3** is a block diagram of a generic lidar system, which shows how these subsystems work together to form a complete lidar.

Transmitter

The transmitter generates light pulses with the required properties and directs them into the atmosphere. Pulsed lasers, with their inherently low divergence, narrow spectral width, and short intense pulses are ideal as the light sources for lidar systems.

In addition to a laser, the transmitter of a lidar often includes a beam expander whose purpose is to reduce the divergence of the beam being transmitted into the atmosphere. This allows a reduction in the background measured by the lidar. At night, the background is due to light from the Moon, stars, airglow, and artificial lights. During the day background is predominately due to the Sun. Background can enter the lidar receiver either directly or after scattering in the atmosphere. A reduction in the divergence of the transmitted beam allows the field-of-field of the receiver to be reduced, resulting in a lower background.

The narrow spectral width of the laser has been used to advantage in a variety of ways in lidar systems. This narrow spectral width allows the spectral filtering of light by the lidar receiver. A band-pass filter tuned to the laser wavelength selectively transmits photons backscattered from the laser

Figure 3 Schematic of a generic lidar.

beam, while rejecting photons at other wavelengths, thereby enabling a reduction in the background by several orders of magnitude. The pulse properties of pulsed lasers allow ranging to be achieved by timing the backscattered signal thus allowing the simpler monostatic configuration.

The major influence on the type of laser used in a lidar is the parameters the lidar is being designed to measure. Some measurements require a very specific wavelength and/or tunability, i.e., resonance-fluorescence and differential absorption lidar (DIAL). These types of lidars can require complex laser systems to produce the required wavelengths, while other simpler lidars, such as Rayleigh, Raman, and aerosol lidars, can operate over a wide wavelength range. Although it may be possible to specify the exact performance characteristics of the laser required of a particular lidar measurement, these characteristics often need to be compromised in order to select from the types of lasers available.

Receiver

The receiver of a lidar collects and processes the scattered laser light before directing it onto the detector. The first optical component, the primary optic, in the receiver usually has a large diameter enabling it to collect a large amount of the scattered laser light.

Lidar systems typically utilize primary optics with diameters ranging from about ten centimeters up to a few meters in diameter. Optics at the smaller end of this scale are used in lidar systems that are designed to work at close range, a few hundred meters, and may be lenses or mirrors. Optics at the larger end of this range are used in systems designed to probe the middle and upper atmosphere and are typically mirrors.

After collection by the primary optic, light is usually processed in some way before being directed to the detector system. Processing can be based on wavelength, polarization, and/or range depending on the purpose for which the lidar has been designed.

As described previously, the simplest form of processing based on wavelength is the use of a narrow-band interference filter to reduce the background. Much more sophisticated spectral filtering schemes are employed in Doppler and high-spectral-resolution lidar systems.

Signal separation based on polarization is a technique that is often used in the study of atmospheric aerosols. Information on aerosol properties can be obtained from the degree to which light scattered from a polarized laser beam is depolarized.

Processing of the backscattered light based on range can be performed in order to protect the detector from the intense near-field returns of high-power lidar systems. This protection is achieved by using a fast shutter that closes the optical path to the detector while the laser is firing and for a short time afterward. The shutter opens again in time to allow transmission of light backscattered from the range being studied.

Detection and Recording

The signal detection and recording section of a lidar takes light from the receiver and produces a permanent record of the

measured intensity as a function of altitude. In the first lidar systems, the detection and recording system comprised a camera and photographic film. Today detection and recording is achieved electronically. The detector is a device that converts light into an electrical signal and the recorder is an electronic device, often part involving a microcomputer, which processes and records this electrical signal.

Photomultiplier tubes (PMTs) are devices used as detectors for incoherent lidar systems working in the visible and ultraviolet. PMTs convert an incident photon into an electrical current pulse large enough to be detected by sensitive electronics. Other devices that are less commonly used as detectors in lidar systems include multianode PMTs, microchannel-plates, and avalanche photodiodes.

There are two ways in which the output of a PMT can be recorded electronically, the pulses can be counted individually (photon counting) or the average current due to the pulses can be measured and recorded (analogue recording). Which of these methods is the most appropriate depends on the rate at which the PMT produces output pulses, which is proportional to the intensity of the light incident on the PMT. If the average time between PMT output pulses is much less than the average pulse width, then individual pulses can be easily identified and photon counting is the more appropriate recording method. However, if the average time between PMT output pulses is close to, or greater than, the average pulse width, then it becomes impossible to distinguish overlapping pulses and so analogue recording becomes the more appropriate method. Some commercially available detection systems are able to simultaneously measure both analog and digital signals from a single PMT, increasing the dynamic range of the PMT by 100 compared to a digital-only counting system.

Coherent Detection

There is a class of lidar systems that determine wind speed by measuring the Doppler shift of backscattered light. There are two ways in which these measurements can be achieved; they are referred to as incoherent and coherent detection. Incoherent systems measure the wavelength of the transmitted and received light independently, using a spectrometer and determine the Doppler shift of the backscattered light from these two measurements. Coherent detection systems use a local oscillator, a narrow-band cw laser, to set the frequency of the transmitted pulses. The backscattered light is then mixed with light from the local oscillator on a photomixer. This arrangement results in the output of the photomixer being a radio-frequency (RF) signal whose frequency is the difference of the frequencies of the local oscillator and the backscattered light. Standard RF techniques are then used to measure and record this RF signal. The measured RF signal is used to determine the Doppler shift of the backscattered light and thus the wind speed.

The Lidar Equation

The lidar equation is used to determine the number of photons detected by a lidar system. The lidar equation takes into

account both instrumental parameters and geophysical variables. The general form of the lidar equation includes all forms of scattering and it can be used to calculate the signal strength for any lidar.

The number of photons detected as pulses at the photomultiplier output, per laser pulse is

$$A \int_{\Delta\lambda} PS(\lambda) \tau_t(\lambda) \tau_r(\lambda) Q(\lambda) \int_{R_1}^{R_2} \xi(r) \tau_a(r, \lambda)^2 \frac{1}{r^2} \times \sum_i \frac{d\sigma_i}{d\Omega}(\lambda) N_i(r) dr d\lambda \quad [1]$$

where,

A is the area of the telescope.

$PS(\lambda)$ is the convolution of $P(\lambda)$ and $S(\lambda)$, where $P(\lambda)$ is the number of photons emitted by the laser in a single laser pulse. $S(\lambda)$ is a function that takes into account any wavelength shift during scattering, including Doppler and Raman shifts. $\Delta\lambda$ is the wavelength range for which $PS(\lambda)$ is nonzero.

$\tau_t(\lambda)$ and $\tau_r(\lambda)$ are the optical transmission coefficients of the transmitter and receiver optics, respectively.

$Q(\lambda)$ is the quantum efficiency of the photomultiplier.

r is the range and R_1 and R_2 are the minimum and maximum ranges for a range bin.

$\xi(r)$ is the overlap factor that takes into account the intensity distribution across the laser beam and the physical overlap of the transmitted laser beam and the field of view of the receiver optics.

$\tau_a(r, \lambda)$ is the optical transmission of the atmosphere along the laser path.

$\frac{d\sigma_i}{d\Omega}(\lambda)$ is the backscatter cross section, for scattering of type i .

$N_i(r)$ is the number density of scattering centers, which cause scattering of type i .

The general form of the lidar equation, as expressed in eqn [1], can usually be greatly simplified when applied to a particular lidar system.

Rayleigh Lidar

Rayleigh lidar is the name given to the class of lidar systems that measure the intensity of light backscatter by molecules from altitudes between about 30 and 100 km. The intensity profiles measured by Rayleigh lidars are used to calculate relative density profiles, which are in turn used to calculate absolute temperature profiles. The terms Rayleigh scattering and molecular scattering are often used interchangeably, as are the terms Mie scattering and aerosol scattering. Rayleigh theory describes the scattering of light by molecules, small compared to the wavelength, and Mie theory describes scattering by aerosols, not small compared to the wavelength, so there is a strong connection between these two pairs of terms.

Rayleigh theory, named after its founder, Lord Rayleigh, describes the scattering of light by objects that are small compared to the wavelength of the incident radiation. Rayleigh scatter explains the color, intensity distribution, and polarization of the blue sky in terms of scattering by atmospheric

molecules. For objects with dimensions greater than about 0.003 times the incident wavelength, the more general Mie theory must be used to calculate scattering effects. Strictly speaking what is commonly referred to as Rayleigh scattering is in fact the sum of pure elastic scattering (the Cabannes line) plus the rotationally excited Raman lines which occur near the Cabannes line. Lidars exist which measure only the pure Cabannes line and the rotational lines (for aerosol properties and temperature respectively).

The Rayleigh backscatter ($\theta = \pi$) cross section for the atmosphere below 90 km can be expressed as

$$\frac{d\sigma_{\text{m}}(\theta = \pi)}{d\Omega} = \frac{C}{\lambda^4} \text{m}^2 \text{sr}^{-1} \quad [2]$$

where the value of C is between about 4.75×10^{-57} and 5.00×10^{-57} , depending on the value used for the index of refraction of air. Above 90 km altitude, the concentration of atomic oxygen becomes significant causing the refractive index of air to change, resulting in eqn [2] becoming less accurate with increasing altitude. The Rayleigh backscatter cross section eqn [2] can be used in conjunction with the lidar eqn [1] to determine the intensity of the backscatter that can be expected for a particular Rayleigh lidar system.

The Rayleigh lidar technique relies on the measured signal being proportional to the atmospheric density; this is not the case in any region that contains aerosols. From the surface to the top of the stratospheric aerosol layer about 25–30 km, the atmosphere contains a significant concentration of aerosols, thus the Rayleigh technique cannot be directly applied to this region. However, the atmosphere above this altitude contains very few aerosols allowing the application of the Rayleigh technique.

The principle of operation of a Rayleigh lidar system is quite simple. A pulse of laser light is fired up into the atmosphere, and any photons that are backscattered and collected by the receiving system are counted as a function of range. The lidar eqn [1] can be directly applied to a Rayleigh lidar system to calculate the expected signal strength. For Rayleigh lidar, a number of simplifications can be made to eqn [1] allowing it to be expressed as,

$$\text{Signal} = K \frac{1}{R^2} N_a(R) \delta R \quad [3]$$

where K is a constant that includes all constant terms from eqn [1], R is the range, δR is the length of a range bin, and $N_a(R)$ is the number density of air. Equation [3] shows that after correction for range, a Rayleigh lidar signal will be proportional to the atmospheric number density profile.

Due to the uncertainty in atmospheric transmission and instrumental parameters it is not possible to determine the value of the constant K in eqn [3] with sufficient precision to enable the determination of an absolute density profile. The measured relative density profile can be scaled to a model density profile to obtain a density profile that is well scaled.

Until recently the only method available to compute temperature from the relative density profile was prescribed by Hauchecorne and Chanin (1980). In this scheme, the relative density profile is integrated, using the hydrostatic equation, to

determine a relative pressure profile. This integration requires an initial or seed pressure, usually chosen from a model atmosphere, to initiate the integration at the maximum altitude of the density profile. The pressure profile calculated in this way has the same ratio to the actual pressure as the relative density profile has to the actual density, i.e., their scaling factors are the same. An absolute temperature profile can be calculated by applying the ideal gas law to the relative density and pressure profiles. The application of the ideal gas law divides the relative pressure by the relative density so that their scaling factors, which are the same, cancel out resulting in an absolute temperature profile.

The selection of the seed for the pressure integration introduces a systematic uncertainty into the temperatures retrieved at the greatest heights. The magnitude of this error is proportional to the difference between the actual pressure and the seed pressure used. As the actual pressure is not known, the resulting error in temperature is unknown. However, the magnitude of this error reduces as the calculation of temperature proceeds downward. **Figure 4(a)** shows differences in temperature profiles retrieved using seed pressures, which differ by ± 1 , 5, and 10% from some initial value. Users of this technique are well advised to ignore temperatures from at least the uppermost 10 km of the retrieval (and more safely 15 km), since the uncertainties introduced by the seed pressure estimate are not easily quantified.

Khanna et al. (2012) have developed a temperature retrieval, which relies on an inversion approach to obtaining

temperature. In this case the temperature profile is varied to find a 'best' match between the measured photocount profile and a photocount profile calculated using the lidar equation. In this method, the temperature is not required to be constant within a retrieval layer and the density profile can be integrated from the bottom to the top of the measurements. These improvements greatly decrease the systematic uncertainty in the seed pressure (or seed temperature). **Figure 4(b)** is in the same format as **Figure 4(a)**, but the temperature profiles are calculated using the inversion approach. The differences in temperature retrieved using an inversion approach introduces a much smaller uncertainty than the traditional method, and useful temperature can be retrieved over the entire measurement range significantly extending the upper altitude of retrieved temperature profiles.

Above about 90 km changes in composition of the atmosphere causes the Rayleigh backscatter cross section and the mean molecular mass to change with altitude. These changes lead to errors in the temperatures derived using the Rayleigh lidar technique. For the current generation of Rayleigh lidar systems there are other sources of error, statistical fluctuations, and seeding error, which are generally larger than those errors due to composition changes above 90 km. However, more powerful Rayleigh lidar systems may ultimately be limited in their maximum altitude extent by composition changes as has been shown by Argall (2007).

Figure 4 Effect of seed pressure choice on the retrieved temperature profile calculated from Rayleigh-scatter lidar measurements: left, the method of Hauchorne and Chanin and right, the inversion approach of Khanna et al. Left: as the initial seed pressure is varied from -10 to $+10\%$ the retrieved temperatures above 85 km are uncertain to a degree which exceeds the statistical uncertainty of the measurement. Right: using an inversion approach the retrieved temperatures are much less sensitive to the initial pressure guess and the retrieved temperature profile is useful over the entire range.

While even the most technically advanced, ground-based, middle-atmosphere lidar systems need clear skies to operate, the addition of Fabry–Perot etalons in the receiver allows daytime measurements. This daytime capability is technically complex and has been implemented on only very few Rayleigh lidar systems.

Doppler Effects

The motion of air molecules has components due to both random thermal motions and wind. When light is scattered by a molecule it suffers a change in frequency due to the Doppler effect. The magnitude and direction of the Doppler shift is determined by the component of the molecules velocity along the direction of the lidar beam.

The random thermal motions of air cause backscattered laser light to be spectrally broadened. Using Maxwell's velocity distribution function and the Doppler equation, it can be shown that the broadening function is Gaussian and has a temperature-dependent width.

Wind, the average motion of air molecules, causes back-scattered laser light to suffer a frequency shift while maintaining its shape. The frequency shift is directly proportional to the component of the wind velocity in the direction of scattering, the radial wind velocity. [Figure 5](#) shows how the spectrum of a narrow-bandwidth laser is modified due to scattering by atmospheric molecules.

Middle atmospheric winds can be determined by measuring the spectrum of backscattered light, however, Rayleigh–Doppler temperature measurements are quite difficult as the signal-to-noise requirements are much greater than those for wind velocity measurement using this technique.

Aerosol Lidar

The theory of scattering that was developed by Mie early this century is a general solution to the scattering of electromagnetic radiation by a homogeneous sphere. This early work has been extended to cover numerous other geometries and so provides a useful approximation for scattering from atmospheric aerosols.

Figure 5 Doppler shift effects on Rayleigh scattering a narrow-line-width laser from atmospheric molecules. The broadening is due to thermal motion and the shift is due to wind. The intensities of the two spectra are not to scale.

The influence of clouds and aerosols on the atmospheric energy budget is complex as they scatter and absorb both incoming solar and outgoing terrestrial radiation. Since the early 1960s a large number of lidar systems have been operated at various stations around the world to study aerosols and clouds in the troposphere and lower stratosphere. Aerosols and clouds are easily detected by elastic backscatter lidar, however, instruments using multiple wavelength transmitters and receivers and polarization techniques provide significantly more information on their properties.

In September of 1994, NASA flew a space shuttle mission, STS-64, which included the LITE instrument, the first successful space-based lidar. LITE was used to measure tropospheric and stratospheric aerosols, clouds, and surface reflectance on a global scale. The next step in space-based lidar was the ICESat mission, which obtained measurements of aerosol and cloud properties from 2003 to 2010. Measurements of backscatter from 532 to 1064 nm were obtained (Schutz et al., 2005).

In June of 2006, the Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation (CALIPSO) payload was launched. CALIPSO is still fully functional as of December 2012 and is routinely acquiring backscatter measurements at both 532 and 1064 nm. Routine data products include aerosol optical depth, backscatter, and extinction in addition to cloud height, thickness, optical depth, extinction backscatter, and properties of water and ice particles (Winker et al., 2007).

Similar measurements of cloud and aerosol properties to those on Earth were also made on Mars in 2008 as part of the NASA Phoenix mission. This highly successful mission found evidence for water on Mars. Whiteway et al. (2009) used the Phoenix aerosol lidar to measure fall streaks from clouds on Mars similar to fall streaks associated with precipitating ice particles on Earth.

Lidar systems can utilize the backscatter from aerosols to measure wind velocity. Light backscattered from aerosols undergoes the same Doppler shift due to wind as light scattered back from molecules. However, the spectral broadening of the light backscattered from aerosols is much narrower than that backscattered from molecules due to the difference in the masses of the two types of scatterers. The high signal level offered by scattering from aerosols in the lower atmosphere allows the use of coherent detection for the determination of wind velocity. Steerable lidars using this technique are capable of making high-resolution wind field maps.

Differential Absorption Lidar

The DIAL technique is used for measuring the concentration of trace species in the atmosphere. The DIAL technique relies on sharp variations in optical transmission near an absorption line of an atmospheric constituent. A DIAL transmits two closely spaced wavelengths, one coinciding with an absorption line of the constituent of interest and the other in the wing of this absorption line. During the transmission of the two wavelengths through the atmosphere the emission that is tuned to the absorption line will suffer greater attenuation than the emission in the wing of the absorption line. The intensities of the two wavelengths that are backscattered to the DIAL

instrument can then be used to determine the optical attenuation due to the constituent and thus the concentration of that constituent.

The DIAL technique has proven to be useful in providing tropospheric measurements with good time and spatial resolution for a number of trace species including NO, H₂O, O₃, SO₂, and CH₄, as well as stratospheric ozone measurements. The Network for Detection of Atmospheric Climate Change (NDACC), an international program, includes a global network of DIAL ozone lidars. DIAL also allows mapping and wide-area monitoring of industrial effluents and pollution.

Raman Lidar

When monochromatic light, or light of sufficiently narrow spectral width, is scattered by a molecular gas or liquid the spectrum of the scattered light can be observed to contain lines at wavelengths different from that of the incident radiation. This effect was first observed by Raman and it is due to the interaction of the radiation with the quantized vibrational and rotational energy levels of the molecule. Raman scattering involves a transfer of energy between the scattered light and the molecule; it is therefore an inelastic process. As the energy levels for each type of molecule are unique and so the Raman spectrum is unique and provides a method of sensing a particular molecular species.

The term Raman lidar is generally used to refer to a lidar that utilizes light scattered by molecules that undergo a change in their vibrational quantum number. Measurement of the intensity of the scattered Raman light allows the calculation of the abundance of the molecular species. The selection of vibrational Raman lines can be achieved with high-quality narrow-band interference filters. However, it is necessary to ensure that the blocking of such a filter is sufficiently high, so that elastic backscatter from molecules and aerosols is effectively attenuated. Due to the small cross sections for Raman scattering, Raman lidar is limited to molecules with a relatively high abundance, such as water vapor and molecular nitrogen, and due to its relative simplicity, is used in preference to DIAL.

Raman lidar is predominately used for the measurement of atmospheric water vapor and temperature. Raman molecular nitrogen profiles can be used to determine atmospheric temperature profiles, using the Rayleigh technique described above, even in regions containing aerosols. Elastic scattering from aerosols can be effectively separated from the Raman nitrogen backscatter by spectral filtering. The Raman nitrogen signal is therefore approximately proportional to the number density profile, although a correction for the optical attenuation of the atmosphere, due to both aerosols and molecules, must be made.

The pure rotational Raman spectrum (PRRS), which is due to scattering involving a change in the rotational quantum state only, is difficult to measure as the spectral shift of the lines is quite small so that separation of the elastic and rotational Raman lines is technically challenging. The separation of lines in the PRRS of N₂ is about 16 cm⁻¹ while the first vibrational transition causes a shift of about 2331 cm⁻¹. The shape of the PRRS is temperature dependent allowing pure rotational Raman lidar to make atmospheric temperature measurements.

Resonance-Fluorescence Lidar

The constant ablation of meteors in the Earth's upper atmosphere leads to the existence of extended layers of alkali metals at altitudes around 90 km. These metals have low abundance but very high resonant-scattering cross sections. Resonant-scattering occurs when the energy of an incident photon is equal to the energy of an allowed transition within an atom. In this elastic process, the atom absorbs a photon and instantly emits another photon at the same frequency. As resonant-scattering involves an atomic transition between allowed energy levels, the probability of this process occurring is much greater than that for Rayleigh scattering, leading to the much higher scattering cross sections. The resonant-scattering cross section for sodium at 589 nm is about 10¹⁵ times larger than the cross section for Rayleigh scattering by air at the same wavelength. As each species of alkali metal has a unique absorption and hence, resonant-scatter and fluorescence spectrum, these may be used to identify and measure the concentration of each individual species. Although most commonly applied to sodium, resonance-fluorescence lidar has been applied to calcium (Ca and Ca⁺), potassium, lithium, and iron.

Sodium lidar systems are used to measure abundance profiles of sodium between 85 and 105 km with time resolution of tens of seconds and altitude resolution of a few hundred meters. Density perturbations due to wave motions are present in the sodium density profiles, enabling the determination of wave parameters in this dynamically active region of the atmosphere to be determined. Spectral resolution of resonance-fluorescence scattering from sodium allows the determination of the temperature and wind. This technique, narrow-band resonance-fluorescence lidar, allows accurate, high resolution, temperature, and wind measurements in the mesopause region. These systems are currently being refined to use all solid-state lasers to generate the required sodium wavelengths and to make more robust systems capable for being used in harsh environments such as encountered on orbital platforms.

Iron Boltzmann lidar uses alexandrite lasers operating at 370 nm to probe the atmospheric iron layer, which exists between about 80 and 100 km. As alexandrite lasers are solid-state lasers and typically very reliable, this technique is particularly well suited to remote operation. Another advantage of this technique is that the wavelength used is in a spectral region where little solar radiation reaches the ground; this allows daytime operation without the need for complex spectral filtering apparatus to reduce the background light levels.

Lidars measuring stimulated emission from atmospheric potassium have also been successfully used to measure atmospheric dynamics and temperatures in a manner similar to sodium (see the review by Chu and Papan, 2005).

Synopsis

This article summarizes the principles and practices of the backscatter lidar techniques used to measure clouds and aerosols in the atmosphere. Scattering phase functions of molecules and particles are presented and polarization techniques are reviewed. The lidar equation is presented with a simple solution that highlights the importance of the backscatter phase function and the use of the extinction-to-backscatter ratio. The technique is illustrated with examples of lidar measurements of stratospheric aerosols, cirrus clouds, and in midlevel ice, water, and mixed-phase clouds. Finally contemporary global measurements of clouds and aerosols by the Cloud Aerosol Lidar with Orthogonal Polarization (CALIOP) lidar aboard the Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO) are described.

Introduction

This article presents several aspects of lidar backscatter. After a general introduction, various definitions pertaining to lidar backscatter are described. This is followed by an explanation of the scattering and backscattering phase functions, including presentation of typical scattering phase functions of molecules, water drops, and clouds. The polarized nature of the radiation and its treatment by a scattering matrix are then described briefly. The lidar equation is presented, together with a simple solution in order to point out the importance of the backscatter phase function and its relation to the extinction-to-backscatter ratio and its use in solving the equation. Examples of extinction-to-backscatter ratios of various atmospheric constituents are presented. Several examples of profiles of measured atmospheric backscatter are described, including stratospheric aerosols, cirrus clouds, and depolarizing effects in midlevel ice, water, and mixed-phase clouds. The article does not cover inelastic backscatter such as Raman scattering and fluorescence.

While current backscatter lidars employ lasers, the first backscatter predates the invention of the laser and employed searchlights. Lidar is used to detect and profile certain constituents in the atmosphere, such as molecules, aerosols, and clouds. The backscatter from such entities is important in lidar because most lidar (laser radar) systems are monostatic, that is, there is a telescope receiver placed close to, or coaxial with, a laser pulse transmitter. Pulses of light sent into the atmosphere are scattered in all directions by molecules, aerosols, and clouds, and a small amount scattered into the back direction is returned to the receiver. The time taken for the laser pulse to return gives the range of the atmospheric volume being studied, and the amplitude of the return is proportional to the volume density of the atmospheric particles or molecules. The total amount scattered by a particle is dependent on the diameter of the particle and its size compared with the wavelength of light. For example, particles that are small compared with the wavelength scatter less than if the scatter were determined solely by the particle's geometric cross section. The ratio of the scattering cross section to the geometric cross section is termed the scattering efficiency and used to quantify the total scattering. The amount scattered in any direction forms a pattern that is described by the single scattering phase

function $P(\theta)$, where θ is the scattering angle that is the angle between the scattered light and the forward direction. The geometry is shown in Figure 1. Backscatter corresponds to $\theta = 180^\circ$, while forward scatter corresponds to $\theta = 0^\circ$.

Backscatter Cross Section, Efficiency, and Coefficient

The scattering cross section $C_{sc}(\lambda, r)$ (m^2) of an atmospheric particle (molecule, aerosol, water drop, or ice crystal) determines how much radiation is scattered in all directions by the particle. Here λ is wavelength and r is the particle dimension. Consider a uniform light beam of irradiance I (W m^{-2}) incident on a particle of area of geometric cross section A (m^2). The particle scatters an amount of power W_{sc} (W) into all directions. The scattering cross section is defined as

$$C_{sc}(\lambda, r) = \frac{W_{sc}}{I}. \quad [1]$$

The scattering efficiency, $Q_{sc}(\lambda, r)$, is defined as the ratio of the scattering cross section to the geometric cross section,

$$Q_{sc}(\lambda, r) = \frac{C_{sc}(\lambda, r)}{A}. \quad [2]$$

Because of the nature of electromagnetic scattering, $Q_{sc}(\lambda, r)$ can approach a value of 2 for nonabsorbing particles that are large compared with the wavelength λ . This is because diffraction occurs around and outside the edges of the particle, causing the scattering cross section to be about $2A$ for large particles. For particles much smaller than the wavelength, the scattering is less efficient and the cross section is much less than $1A$.

The backscatter cross section $C_{\Pi}(\lambda, r)$ ($\text{m}^2 \text{sr}^{-1}$) determines the amount of power scattered into the backscattering direction per unit solid angle. The backscatter efficiency $Q_{\Pi}(\lambda, r)$ is again the ratio of the scattering cross section to the geometric cross section. The backscatter phase function, as well as the total scattering efficiency, determines the backscatter efficiency, as shown under 'scattering phase function' below.

When lidar is observing the atmosphere, it is observing the molecular atmosphere into which are mixed aerosols and clouds in different proportions and varying in both time and space. Of course, aerosols and clouds – particularly clouds – tend to form

Figure 1 Schematic of backscattering at an atmospheric particle.

in well-defined layers, whereas gas molecules are distributed throughout the atmosphere, the molecular density depending on the local pressure and temperature. Aerosols and clouds generally contain a range of particle sizes with different number densities, defining a smooth particle number size distribution. The backscatter efficiency also varies with particle size. Lidar measures the returns within a volume of the atmosphere and the volume backscatter coefficient $\beta(\lambda)$ ($\text{m}^{-1} \text{sr}^{-1}$) is defined as

$$\beta(\lambda) = \int_0^\infty Q_\pi(\lambda, r) n(r) \pi r^2 dr, \quad [3]$$

where $n(r)$ is the number of particles of dimension r , and in the case illustrated above the particles are spheres (a water cloud, for example) of radius r . For ice crystals, such as hexagons, the

Figure 2 The scattering phase function for scattering from a molecule – Rayleigh scattering. Labels are described in the text. Adapted with permission from Twomey, S., 1977. *Atmospheric Aerosols*. Developments in Atmospheric Science, vol. 7. Elsevier, Amsterdam.

dimensions and area depend on the crystal type or habit and orientation. Irregular particles are often modeled as equivalent spheres. If the ice crystals are tumbling then an effective dimension has to be determined.

Scattering Phase Function

The phase function $P(\theta)$ defines the intensity of the radiation scattered by a particle at an angle θ to the forward direction. The total scattered radiation normalized to 4π is then

$$\int_0^{180} P(\theta) \cos \theta \sin \theta d\theta = 4\pi. \quad [4]$$

The value of the backscatter phase function, together with the scattering efficiency, will determine the backscatter efficiency. This can be either larger or smaller than the isotropic backscatter efficiency of 0.0796, depending on whether the scattering phase function is peaked or depressed near the backscattering direction.

We now consider some phase functions for a range of atmospheric constituents and the corresponding backscatter phase function and efficiency. The single scattering phase function for an atmospheric molecule is shown in Figure 2. As noted above, the phase function denotes the fraction of the total radiation that is scattered into a given angle to the incident direction. Note that the scattering differs according to the polarization of the radiation. For scattered radiation in a plane containing the direction of polarization and the vector of the incident radiation, denoted by l , the phase function falls to 0 at a scattering angle of 90° . For the radiation perpendicular to the plane containing the incident vector, denoted by r , scattering is independent of direction. The scattering direction in Figure 2 is depicted in a polar diagram where incident radiation is entering from the left of the diagram. The normalized scattering phase function for unpolarized light is given by

$$P(\theta) = \frac{3}{16\pi} (1 + \cos^2 \theta). \quad [5]$$

The backscatter phase function $P(\pi)$ is then $6/16\pi$ (0.119 sr^{-1}).

For particles of molecular size, or of dimensions small compared with the wavelength, Rayleigh scattering theory is appropriate. For particle dimensions approaching, or larger

than, the wavelength of the incident radiation, Mie scattering theory is appropriate. Figure 3 shows the polar scattering diagram for a water sphere, as might be found in a water cloud. The diagram shows a succession of high and low values of scatter, caused by complex interference effects between penetrating and surface waves on the sphere. The quantity r is the radius of the sphere and x is the size parameter, $2\pi r/\lambda$. The backscatter phase function, which is not normalized, is seen to be small compared with the forward scattering. This is a characteristic of scattering on large particles, with some exceptions, as we will see. The phase function depicted here is the sum of the two directions of polarization (see Polarization Effects section).

Figure 4 shows typical scattering phase function for a hexagonal ice crystal that has large dimensions relative to the wavelength. The presentation is different, with scattering angle on the x -axis and phase function on the y -axis. The scattering peak at 22° that gives rise to the halo is clearly visible. Again one can see that the backscatter phase function is quite low, and much lower than that from a molecule. Of course, the cross sections of ice clouds are much greater per unit volume than for molecules, so that backscatter intensity from ice clouds tends to be greater, although this is not always the case. The crystal phase function is calculated either from a complex geometrical theory or by geometrical ray tracing.

What is relevant here to lidar backscatter is the large differences in the backscatter phase function between the various atmospheric components in Figures 2–4. These differences can be exploited in lidar systems as the phase function varies with size parameter. Lidar systems with multiple wavelengths can be used to estimate the size of particles based on the relative differences in backscatter at each wavelength.

Figure 3 Scattering phase function for a water drop. The size parameter and water droplet size are shown below. Adapted with permission from Twomey, S., 1977. *Atmospheric Aerosols*. Developments in Atmospheric Science, vol. 7. Elsevier, Amsterdam.

The backscatter-to-extinction ratio k (sr^{-1}) is

$$k = \frac{\beta}{\sigma} = \frac{Q_\pi}{Q_{sc}} = P(\pi), \quad [6]$$

where β ($\text{m}^{-1} \text{sr}^{-1}$) is the backscatter coefficient, σ (m^{-1}) is the volume extinction coefficient, Q_{sc} is the effective scattering efficiency, and Q_π is the backscatter efficiency of the volume of particles. The backscatter-to-extinction ratio is numerically equal to the normalized backscatter phase function. The value of k is needed to solve the backscatter lidar equation for volume attenuation of the lidar beam and is therefore a crucial quantity to lidar backscatter measurements. A popular quantity is S , defined as the lidar ratio, which is simply the reciprocal of the backscatter-to-extinction ratio and therefore is measured in steradians. Typical ranges of values of S and k are shown in Table 1. Note that aerosol populations also possess a range of values of these quantities.

Polarization Effects

Thus far we have considered the total radiation backscattered by a particle without consideration of whether the light is polarized or not. In fact, pulsed lasers used in lidar are usually linearly polarized to a high degree. The backscattered light can have significantly different polarization based on the scattering properties of the particles and their orientation. A complete analysis of the polarization effects can be conducted using Stokes parameters. However, nearly all lidar systems employ linear depolarization effects where the backscattered light is split into two channels. In one channel, the light passes through a polarizer parallel to the polarization of the transmitted light and in the other channel, it passes through a polarizer perpendicular to the polarization of the transmitted light. The degree of depolarization is given by the amount of signal in the perpendicular channel and used to discriminate between different constituents. Molecules and water spheres have only very weak depolarization due to their electronic properties. Ice crystals and aerosols, however, are found to depolarize by various amounts.

Scattering of radiation is conveniently described by a scattering matrix, whose components can be measured by optical instruments. Here, we consider a backscattering matrix for nonspherical particles as a general example (Sassen, 2000):

$$F(180) = \text{diag}[F_{11}(180), F_{22}(180), F_{33}(180), F_{44}(180)], \quad [7]$$

This matrix is simplified as it applies to particles that are randomly oriented in space and which contain a plane of symmetry, such as typical hexagonal crystals. The medium is called macroscopically isotropic and symmetric. If there is horizontal orientation of ice crystals, which can occur, then more scattering elements in the matrix need to be considered. The present treatment represents the present state of progress in the field.

In terms of the above matrix a depolarization ratio Δ , defined as the ratio of the perpendicular to parallel components, is given by

$$\Delta = \frac{F_{11}(180) - F_{22}(180)}{F_{11}(180) + F_{22}(180)}. \quad [8]$$

Figure 4 Scattering phase function for an ice crystal; schematic representation from a number of experimental phase functions. Adapted with permission from Platt, C.M.R., 1981. Remote Sounding of High Clouds. III: Monte Carlo Calculations of Multiple-Scattered Lidar Returns. *Journal of Atmospheric Sciences* 38, 156–167.

Table 1 Range of values of backscatter parameters k and S for various atmospheric scatterers

Atmospheric constituent	k (sr^{-1})	S (sr)
Molecular	0.119	8.4
Water cloud	0.047–0.050	20.0–21.3
Ice cloud theoretical	0.008–0.072	14–125
Ice cloud experimental	0.011–0.036	28–91
Aerosol	0.015–0.05	20–60

Now, for spheres, $F_{11}(180) = F_{22}(180)$, so that $\Delta = 0$ is a well-known result for this case, although there is some residual depolarization.

Hexagonal crystals depolarize because the laser radiation undergoes several internal reflections before ending up in the back direction, so that (except for specular reflections at perpendicular surfaces) some rotation of the plane of the polarization vector occurs. Measured values of depolarization ratio are quite large in cirrus clouds, which allows some distinction in cloud phase using a depolarization lidar.

The use of such a lidar in such observations is thus very desirable.

The Lidar Equation

Lidar is used to measure the properties of atmospheric layers through their backscattering and depolarization properties. As the layers scatter the laser beam, then they also attenuate the beam during passage through that layer. Thus we must understand the retrieval of the backscatter coefficient of a particular layer. Measured backscatter must be corrected for this attenuation. It is apparent then as to how the extinction-to-backscatter ratio S of a volume of particles is important to the retrieval process. The lidar equation can be written in the first place in terms of the power $P(r)$ measured from a particular range r :

$$P(r) = \frac{EAc}{r^2} (\beta_{pa} + \beta_{pe}) \exp \left\{ -2 \int_{r_1}^{r_2} \sigma(r) dr \right\}, \quad [9]$$

where E is the pulse energy, A the telescope area, and c the velocity of light. The backscatter coefficient β is the sum of

the two polarization components in the parenthesis and $\sigma(r)$ is the volume extinction coefficient of the layer within ranges r_1 and r_2 . The power is calibrated against that from a molecular layer at a different range. The lidar (eqn [9]) can then be written:

$$\beta'(r) = \beta(r)T_{12}^2, \quad [10]$$

where

$$\begin{aligned} T_{12}^2 &= \exp - 2 \int_{r_1}^{r_2} \sigma(r) dr \\ &= \exp - 2S \int_{r_1}^{r_2} \beta(r) dr, \end{aligned} \quad [11]$$

and we consider $\beta(r)$ as the sum of the two polarization components.

The solution for $\beta(r)$ in eqns [10] and [11] is then

$$\beta(r) = \frac{\beta'(r)}{1 - 2S \int_{r_1}^{r_2} \beta'(r) dr}. \quad [12]$$

The crucial importance of the quantity S in the solution is clear.

The solution is generally more complex, as there is the molecular atmosphere to consider. The above is an example of how a volume backscatter coefficient can be recovered if we know the extinction-to-backscatter ratio S .

Table 1 shows the values of k and S for various atmospheric constituents from both experimental and theoretical data.

Backscatter lidar has also been used at infrared wavelengths where the absorption by both water and ice can be quite strong. In that case, the scattering efficiency and backscatter efficiency will be correspondingly less for transparent particles. The same is true for some aerosols, such as those composed of soot where strong absorption of visible radiation can occur. Values of S will be correspondingly larger than for the transparent-particle case.

Measurements of Atmospheric Backscatter

Early lidar observations were made of the stratospheric aerosol, which responds to large volcanic eruptions. Such eruptions send a cloud of enhanced aerosol mass around the globe that is easily observed by lidar. Series of observations now exist covering 30 years that show how peak backscatter in the Junge layer has varied over the years and how it responds to volcanic activity. An example is shown in Figure 5. The total backscatter is a mixture of aerosols and molecules. A model of molecular backscatter from local meteorological information is shown, and the enhanced backscatter in the stratosphere is indicated clearly. The aerosol backscatter amplitude waxes and wanes in strength over the years as various volcanic clouds appear and then dissipate.

The atmospheric boundary layer also contains copious amounts of aerosol as a capping temperature inversion impedes upward movement out of the layer. Such aerosol layers can be dense in large urban areas, in regions of desert dust, and from forest fires, as examples.

Cirrus was also an early target of investigation because of the semitransparent nature of such clouds. The Sun's disk is often seen hazily through even quite deep layers of cirrus. Lidar pulses of radiation can often penetrate through such layers with sufficient photons returning to the receiver to be detectable.

Figure 5 Typical backscatter profile (in units of range squared) for the stratospheric aerosol layer. The backscatter for a model molecular atmosphere is also shown. Adapted with permission from Kent, G.S., Clemesha, B.R., Wright, R.W., February 1967. High altitude atmospheric scattering of light from a laser beam, *Journal of Atmospheric and Solar-Terrestrial Physics* 29 (2), 169–181.

Figure 6 shows a typical return from cirrus, the depth being rather typical for such clouds. Attenuation is fairly weak for this cloud. The figure also reveals typical structure with variations in backscatter with altitude. The Mt. Pinatubo volcanic cloud was strong at the time this profile was taken and shows through the cirrus. When several profiles taken at successive time intervals are investigated, cirrus ice crystals falling out and being swept sideways by the wind are revealed. There is often also an indication of cirrus cloud base becoming progressively lower with time.

Examples of linear depolarization ratio are shown in Figure 7. Here, layers of midlevel cloud exhibit very variable characteristics. This is because layers of ice crystals, water drops, and mixed-phase cloud can exist separately in the atmosphere. The lidar backscatter is shown as the full line and the depolarization ratio Δ as the broken line. The bottom layer just above 4 km has a value of Δ that is typical of ice clouds. The next layer has intense backscatter but very low values of depolarization. This is an interesting case that is fairly common at these altitudes and temperatures. Between atmospheric temperatures of -10 and -20 °C, ice crystals are often hexagonal plates that float horizontally through the air. They thus present a large area of cross section but also mirrorlike surfaces, which do not depolarize in the backward direction. If the lidar is tilted a few degrees off the horizontal, such returns disappear rapidly, indicating the close angle to horizontal at which the crystals fall. Such

Figure 6 Typical backscatter profile from a cirrus cloud, showing the strong backscatter and atmospheric attenuation. unusual and dramatic returns from the atmosphere show the strength of lidar backscatter in picking out details in cloud layers. The layer at about 4.5 km is probably composed of ice, with some supercooled water drops possibly also present. The top layer is interesting because there appears to be strong attenuation and a pattern of depolarization ratio that commences at the cloud base with a low value but increases steadily upwards. This happens to be the characteristic of a layer of water drops. Because these are relatively small and numerous, attenuation is quite strong. The depolarization pattern is a consequence of strong multiple scattering in the beam, where the scattered photons near the back direction, or even at larger angles, can be scattered several times more, thus finding their way back into the telescope receiver beam. This process can, in a manner equivalent to crystal internal reflections, rotate the plane of polarization to give depolarization in the back direction.

Global measurements of aerosols and clouds have entered a new phase with the launch of the CALIPSO satellite mission in 2006. The CALIPSO satellite carries CALIOP, a nadir viewing two-wavelength, polarization sensitive lidar. The CALIOP wavelength and polarization capabilities allow discrimination between aerosol and cloud particles just as they have been employed in earlier ground-based lidar systems. However, being satellite-borne, CALIOP measurements allow scientists to explore upper- and middle-level clouds that are often shielded from surface-based observers by low-level clouds. Furthermore, the CALIOP measurements are made as part of a suite of instruments aboard CALIPSO and companion satellites that includes imagers, radiometers, and radars. Meteorological studies seek to understand the roles of clouds and aerosols as well as the interactions between them. The CALIOP measurements have mapped aerosol layers above clouds where the heating effects of aerosols are enhanced by the underlying clouds. These aerosol layers were previously unobserved and are now being incorporated into assessments of aerosol radiative forcing. CALIOP measurements have also provided a more accurate detection of clouds than earlier imaging satellites, as the lidar detects both upper- and lower-level clouds. The lidar measurements have revealed significantly higher occurrence of stratus decks over the Pacific and Atlantic Oceans than previously reported. Furthermore, the lidar has the sensitivity to detect thin cirrus clouds that have been previously unreported. These thin cirrus clouds have significant impact on the radiative budget of the tropical upper troposphere and are understood to influence troposphere–stratosphere exchange.

The above examples show the power of lidar backscatter to distinguish various layers of aerosols and clouds in the

atmosphere and understand their meteorological impacts. Lidar backscatter has established itself as a key remote-sensing technique in understanding the role of aerosols and clouds in the Earth's climate system.

Synopsis

Differential absorption lidar (DIAL) is a laser remote-sensing technique that is used for range-resolved (profile) measurements of atmospheric gas concentrations. Technological advancements in DIAL systems have greatly increased the measurement capabilities of ground-based and airborne DIAL systems for measurements of tropospheric and stratospheric O_3 and tropospheric H_2O , along with pollution measurements of many other gases in range-resolved and column measurements. The DIAL technique has also been proposed for measurements of H_2O and O_3 from space, and a variation of the DIAL technique called integrated path DIAL (IPDA) is being explored for global, high-precision column measurements of CO_2 and CH_4 . All of these topics are discussed in this article.

Introduction

Differential absorption lidar (DIAL) is a laser remote-sensing technique that is used for range-resolved (profile) measurements of atmospheric gas concentrations. This technique was first applied in 1966 for remote measurements of water vapor (H_2O), and since then it has been used to measure other naturally occurring atmospheric gases such as ozone (O_3) and many pollutant gases, such as sulfur dioxide (SO_2), nitrogen dioxide (NO_2), ammonia (NH_3), mercury (Hg), carbon monoxide (CO), carbon dioxide (CO_2), and hydrocarbons. While the initial DIAL technique development focused on H_2O , the main thrust of the DIAL applications in the 1970s and early 1980s was on pollution monitoring. The first airborne measurements with DIAL were aimed at studying tropospheric O_3 in large-scale pollution studies over the East Coast of the United States in 1980. Subsequently, airborne DIAL measurements of H_2O were demonstrated in 1982. Technological advancements in airborne DIAL systems have greatly increased the measurement capabilities of ground-based and airborne DIAL systems for measurements of tropospheric and stratospheric O_3 and tropospheric H_2O , along with pollution measurements of many other gases in range-resolved and column measurements. Even the possibility of DIAL profile measurements of carbon dioxide (CO_2) and methane (CH_4) are being investigated. The DIAL technique has also been proposed for measurements of H_2O and O_3 from space, and a variation of the DIAL technique, called integrated path differential absorption lidar (IPDA), is being explored for global, high-precision column measurements of CO_2 and CH_4 . All of these topics are discussed in this article.

DIAL Technique

DIAL is a remote-sensing technique that uses two lidar returns to determine the distribution of a selected gas along the direction of the lidar beams. A simplified version of the DIAL concept is shown in Figure 1. The molecules and aerosols in the atmosphere provide the backscattering media for the laser light via Rayleigh and Mie scattering, respectively. Two laser wavelengths are employed, one tuned to a strong absorption feature

of the gas of interest, generally called the 'on' wavelength (λ_{on}), and the other tuned to a nearby wavelength with weak absorption by the gas, generally called the 'off' wavelength (λ_{off}). The value of the average gas concentration N_A in the range interval from R_1 to R_2 can be determined from the ratio of the backscattered lidar signals at λ_{on} and λ_{off} , as shown in Figure 1. In that equation, $\Delta\sigma = \sigma_{on} - \sigma_{off}$ is the difference between the absorption cross-sections at the on and off wavelengths, and $Pr_{on}(R_1)$ and $Pr_{off}(R_2)$ are the signal powers received from range R at the on and off wavelengths, respectively. This equation is essentially an application of the familiar Beer-Lambert law for an absorbing medium. The λ_{off} lidar return also provides important information on the molecular and aerosol-scattering properties of the atmosphere, and this contributes greatly to the science interpretation of the gas profile measurement.

Some of the key considerations for being able to use the DIAL technique for measuring range-resolved gas concentrations include:

1. having a tunable, pulsed laser source that can generate sufficient pulse energies at the DIAL wavelengths on and near a suitable absorption feature of a gas of interest, with the λ_{on} and σ_{on} optimized so that the integrated absorption by the gas at the maximum measurement range has a one-way optical depth of about one. This ensures an optimum compromise between having a large $\Delta\sigma$ and having enough signal from the most distant range to be able to make a DIAL measurement;
2. keeping the DIAL wavelengths as close together as possible in order to minimize measurement errors that result from differences in the atmospheric scattering and attenuation at these two wavelengths. When the laser wavelength separation is unavoidably large, a correction to account for wavelength differences in atmospheric scattering and attenuation must be applied;
3. selecting a DIAL wavelength region where the atmospheric scattering is sufficient to provide adequate backscattered signals from the atmosphere. Molecular scattering drops off as λ^{-4} and is very weak for wavelengths longer than about $1\ \mu m$. Thus, for longer wavelengths (typically longer than $1\ \mu m$), aerosols, clouds, or some sort of surface has to provide the backscattered signal. For species that are

Figure 1 The differential absorption lidar (DIAL) concept.

- measured in the thermal infrared spectral region (3–12 μm), gas profile measurements are generally constrained to the planetary boundary layer (mixing layer), although long-path measurements can be made using topographic targets;
4. minimizing unknown absorption interference from other gas species;
 5. using lasers with short pulse lengths compared to the desired measurement range resolution. For example, a 100 ns laser pulse length has a 15 m folded scattering length; and
 6. using detectors with the necessary sensitivity and low noise level for making the DIAL measurements.

Three types of lasers are being used in the development of new DIAL systems in the ultraviolet (UV) to infrared (IR) spectral region: rare-earth solid-state lasers that have a limited (<100 nm) tuning range, custom-designed optical parametric oscillators, and fiber lasers. In some instances, the laser frequency is doubled or tripled to achieve wavelengths in the UV and visible (VIS) spectral regions. For narrow-band DIAL systems operating on single absorption lines in absorption bands in the IR, the spectral position and width are controlled by locking the laser frequency of a seed laser with respect to an absorption feature and by injection seeding the laser transmitter. DIAL detectors of choice include photomultiplier tubes (PMTs) in the UV to mid-VIS region, avalanche photodiodes (Si:APDs) in the mid-VIS to about 1 μm region, and InGaAs:APD in the 1.0–1.7 μm region. New mercury-cadmium-telluride (HgCdTe) detectors are being developed for use in the 1–4.5 μm region. Detector noise corrupts measurements in long-wavelength (>2 μm) regions, and in these cases, heterodyne detection methods are employed to overcome detector noise.

Note that the DIAL technique generally performs better in the nadir direction than in the zenith because molecular density and, in general, aerosol scattering decrease with increasing altitude, so that the backscattered lidar signal falls off more rapidly in the zenith than in the nadir. Thus, the DIAL technique is well suited for operation from airborne platforms, especially for relatively well-mixed gases such as O_3 , H_2O , and CO_2 . Zenith measurements from aircraft platforms at wavelengths greater than 1 μm are in general more difficult because of rapid reduction in molecular and aerosol backscattering at higher altitudes. Airborne DIAL systems have demonstrated measurement accuracies better than 5% in the troposphere for H_2O and in the troposphere and lower stratosphere for O_3 . To achieve these accuracies, data from these DIAL systems are generally averaged over 200–500 m in vertical distances and over 10–70 km in horizontal distances. Airborne DIAL systems have the ability to measure gas concentrations over long ranges (~1000 km) and map their distribution over regional scales for application to studies of atmospheric processes. Aerosol-scattering profile information is simultaneously obtained from these DIAL systems with much higher spatial resolutions (~30 m in the vertical and <200 m in the horizontal). Atmospheric CO_2 measurements for climate studies require an accuracy of <0.3%. Rapid progress has been made recently to demonstrate this capability from airborne lidar systems.

In designing and operating DIAL systems, one must be aware of a number of atmospheric and instrumental effects that can cause bias in the measurements, including scattering and extinction differences between on and off wavelengths, sensitivity of absorption and scattering to atmospheric temperature and pressure, interference due to other absorbing species, laser spectral characteristics, background radiation, detection system

noise, and so on. A well-designed and optimally operated DIAL system reduces these errors to a manageable, if not insignificant, level. In some cases, these biases are minimized or removed during data processing.

Use of Topographic Targets

When the DIAL measurement does not have sufficient atmospheric backscatter or does not have range resolution for a gas profile measurement, or there is a requirement for a very high-precision measurement, such as for CO_2 and O_2 , a topographic target may be employed to provide the backscattered laser radiation. This DIAL measurement results in a long-path or column measurement of the gas, which is known as an IPDA measurement. Low-pulse-energy high-repetition-rate laser systems and intensity-modulated (IM) continuous-wave (CW) laser systems often need to use the IPDA method. There are several issues that need to be addressed when using topographic targets, including (1) the need for accurate range information that can be achieved by proper design of the pulsed or pulse-encoded laser systems and during their associated data retrieval methods; (2) rapid variations in the height of topographic targets that can be minimized either by simultaneous measurements of on and off signals from these targets or by randomizing these effects by collecting a large number of samples; (3) the introduction of bias in IPDA measurements due to very sharp spectral changes in the reflection features of the materials contained in the topographic targets, which can be reduced by selecting closely spaced on and off wavelengths; and (4) interferences in IPDA measurement by intervening clouds and aerosols that need to be compensated for, particularly when using IM-CW measurement techniques. Another factor to consider is that unless the target is moving, such as from an aircraft or satellite, or is being scanned, the measurement accuracy will not necessarily increase rapidly with the number of pulses averaged.

Application Areas

The primary applications of the DIAL technique have been in the areas of O_3 and H_2O measurements. These gases are of great importance in such areas as atmospheric chemistry, radiation, health, and weather, and they are discussed in detail in this article. A number of other gases have been or can be studied using the DIAL technique. Although H_2O was the first gas measured with the DIAL technique (via the temperature-tuned ruby laser lidar system in 1966), NO_2 was the first pollutant gas measured using this technique in the early 1970s. NO_2 is the only gas of interest with a strong absorption band in the VIS spectral region, with features in the blue region. However, since NO_2 occurs in low concentrations in most situations, appearing at high concentrations only in major pollutant plumes, there has not been significant activity in measuring it using DIAL. SO_2 has been measured using dye lasers operating in the UV spectral region near 300 nm, where it has a strongly modulated absorption spectrum. The interest in SO_2 was primarily related to emissions from power plants, but there has also been some interest in SO_2 emitted from volcanoes. Hg is another gas of interest. Hg has a strong absorption line near 254.3 nm, and it is emitted from

a number of sources, including chlorine-alkali plants, geothermal fields, volcanoes, cinnabar mining areas, and coal-burning power plants. Hydrocarbons have seen some interest as well. The absorption bands vary from near 300 nm for benzene to 3.4 μm for methane and 10.5 μm for ethylene. Other hydrocarbons can also be measured in the 3.2–3.7 μm and 9.3–10.7 μm spectral regions. Hydrocarbons have various urban and industrial sources, and it can often be cost-effective to use laser systems to detect hydrocarbon gas leaks in industrial plants so they can be eliminated. NH_3 is commonly found near feedlots and other agricultural operations, and it has absorption lines in the 9.3–10.7 μm spectral region, which can be accessed by CO_2 laser transmitters operating in that region.

There is also increasing interest in the measurement of CO_2 due to its importance in global climate change and the carbon cycle. The sources and sinks of atmospheric CO_2 are not well understood on a global scale, and there is a need to map the large-scale sources and sinks of CO_2 , preferably from space. There are candidate absorption lines in the 1.6 and 2 μm spectral regions, and fiber-based and solid-state laser technology is being developed in these regions for possible space-based IPDA systems. CO_2 is difficult to measure in part because it is a long-lived gas and has a relatively high 'background' concentration, which does not vary much around the Earth. As a result, the measurement accuracy and precision must be extremely high for meaningful measurements. Also, it is important to measure the atmospheric mixing ratio of CO_2 , and thus it will be important to measure atmospheric number density, via an IPDA O_2 column measurement, to convert CO_2 concentrations to CO_2 mixing ratios.

Airborne DIAL Systems and Applications

Determining variations of O_3 and H_2O over large geographic regions is important to our understanding of a broad range of atmospheric processes. For example, measurements of O_3 and H_2O distributions can lead to an improved understanding of the relative role of transport versus photochemistry in the tropospheric O_3 budget. O_3 and H_2O are important radiatively and contribute to the radiation budget and climate change. H_2O is influential in many different meteorological processes and in the transport of energy on large scales. Better knowledge of upper tropospheric and lower stratospheric water vapor is needed to understand the dynamics and chemical processes in this region and for climate studies. For a better understanding of the atmosphere, it is important to study the spatial and temporal variations of these gases over many regions of the Earth and ultimately be able to make measurements of them from space. Lidar systems have the potential to provide the high vertical resolution needed in these studies. DIAL measurements of O_3 and H_2O were initially demonstrated from the ground. Ground-based O_3 DIAL systems are being used to monitor air quality and to study stratospheric changes, and ground-based water vapor DIAL systems are being used in meteorological studies. Airborne DIAL systems evolved from ground-based DIAL systems and are used in many field experiments to study a number of atmospheric chemical, dynamical, transport, and meteorological processes.

Airborne DIAL systems are also considered precursors to the development of space-based DIAL systems for making global-scale measurements.

Airborne O₃ Measurements

The first airborne DIAL system was flown for O₃ and aerosol investigations, and it was performed in conjunction with a large-scale pollution field experiment conducted over the East Coast of the United States in the summer of 1980. This initial system evolved into the advanced UV DIAL system that has been used in many airborne field experiments over the last two decades. A schematic of the UV DIAL system is shown in [Figure 2](#). This system uses four frequency-doubled Nd:YAG lasers to pump sequentially two dye lasers that are frequency-doubled into the UV to produce on- and off-line wavelength pairs of 289 and 300 nm or 301 and 310 nm for DIAL O₃ measurements in the troposphere or stratosphere, respectively. The parameters of the O₃ DIAL system are given in [Table 1](#). The residual 1064 and 590 nm beams from the frequency-doubling processes of the Nd:YAG and dye lasers, respectively, are also transmitted for aerosol and cloud measurements. This system has a demonstrated absolute accuracy for O₃ measurements of better than 5% or 2 ppbv (parts per billion by volume), whichever is larger, and a measurement precision of 2% or 1 ppbv with a vertical resolution of 300 m and an averaging time of 5 min (a horizontal resolution of about 70 km at typical aircraft ground speeds). An example of the O₃ measurements made with this system is shown in [Figure 3](#). This figure shows many different aspects of O₃ processes that occur from the tropics to high latitudes, including photochemical loss and production, vertical and horizontal transport, and stratosphere–troposphere exchange.

The NASA Langley airborne UV DIAL systems have made significant contributions to the understanding of O₃ in both the troposphere and stratosphere. One of the key features of these measurements has been the characterization of the air masses using simultaneous O₃ and aerosol properties. This

characterization has led to the identification of photochemical, meteorological, dynamical, and transport processes in the atmosphere. These DIAL systems have been used in 26 international and 3 national field experiments during the past 30 years; during these field experiments, measurements were made over, or near, all of the oceans and continents of the world. A list of field experiments and base locations for these airborne field experiments is given in [Table 2](#). Data derived from these field experiments are publicly available from NASA's Langley Research Center.

Airborne H₂O Measurements

The first DIAL measurements of H₂O with a continuously tunable laser were demonstrated in the late 1970s. In an initial step toward the development of a space-based H₂O DIAL system, the first airborne H₂O DIAL system was developed and demonstrated in 1982. This system was based on Nd:YAG-pumped dye laser technology, and it was used in the first airborne H₂O DIAL investigation of the marine boundary layer over the Gulf Stream. This laser was later replaced with a flashlamp-pumped solid-state alexandrite laser, which had high spectral purity (>99% of laser energy contained within a narrow 1 pm spectral region), and this system was used to make accurate H₂O profile measurements across the lower troposphere under a variety of atmospheric conditions. A third H₂O DIAL system called Lidar Atmospheric Sensing Experiment (LASE) was developed as a prototype for a space-based H₂O DIAL system. This system was designed to operate autonomously from a high-altitude ER-2 aircraft, and it uses a Ti:sapphire laser and 1–3 different H₂O absorption cross-sections to make H₂O measurements across the entire troposphere. While the LASE system was initially designed for operation from NASA's high-altitude ER-2 aircraft, it was also modified to fly on conventional medium-altitude P-3 and DC-8 aircraft.

The Ti:sapphire laser in LASE is pumped by a double-pulsed, frequency-doubled Nd:YAG to produce laser pulses

Figure 2 Configuration of the NASA Langley airborne UV DIAL system is shown on the left panel. Four beams are simultaneously transmitted in the nadir and zenith directions for measurements of O₃ profiles with DIAL wavelengths of 289 and 300 nm and for aerosol and cloud profiles at 600 and 1064 nm. The right panel shows a photograph of the DIAL system as configured on the DC-8 aircraft.

in the 815 nm absorption band of H₂O. The wavelength of the Ti:sapphire laser is controlled by injection seeding with a diode laser that is frequency-locked to an H₂O line using an absorption cell. Each pulse pair consists of an on-line and off-line wavelength for the H₂O DIAL measurements. Parameters of the LASE system are shown in Table 3. Operation of LASE

on the side of the H₂O absorption line permits the use of the same H₂O line for different absorption cross-sections, and as a result, the DIAL measurements of H₂O can cover four orders of magnitude of dynamic range. The accuracy of LASE H₂O profile measurements was determined to be better than 6% or 0.01 g kg⁻¹, whichever is larger, over the full dynamic range of

H₂O concentrations in the troposphere. LASE measurements of water vapor, aerosol, and cloud distributions have been used in many atmospheric-process and hurricane model forecast studies. An example of LASE measurements of water vapor in the vicinity of Hurricane Erin on 10 September 2001 is shown in Figure 4. LASE operated onboard the DC-8

aircraft at an altitude of 9 km, and the flight track of the DC-8 is shown in the left panel in Figure 4. Elevated and highly variable water vapor distributions, shown in the right panel of Figure 4, were observed up to and above the aircraft. These data and data from other NASA hurricane field experiments have been used at Florida State University to conduct hurricane model forecast studies. These studies have shown that inclusion of LASE water vapor measurements improved model forecasts of hurricane track and intensity. LASE has participated in 12 major airborne field experiments since 1995. A list of field experiments and their base locations is given in Table 4. During the last decade, the German Aerospace Center (DLR) has developed an airborne DIAL system operating in a strong H₂O band near 940 nm. This system has been flown on a Falcon 20 aircraft to measure upper tropospheric and lower stratospheric moisture profiles. The 940 nm band has much stronger H₂O absorption lines than the 820 nm band and is more suitable for moisture profiling in the upper troposphere and lower stratosphere, where the concentrations of H₂O are very low and variable. Measurements of water vapor in the upper troposphere and lower stratosphere are needed in climate studies. An example of upper tropospheric and lower stratospheric water vapor measurements by the DLR DIAL system is shown in Figure 5. This example shows variations of water vapor mixing ratios

across a tropopause fold region where there is a potential for exchange of air between the stratosphere and troposphere.

Airborne Column CO_2 Measurements

The first high-precision CO_2 column measurements with the IPDA method were demonstrated from an aircraft in 2008. These measurements were made by a multifrequency, single-beam laser absorption spectrometer (LAS) operating in the vicinity of a CO_2 absorption line in the $1.57 \mu\text{m}$ region. The LAS system uses an IM-CW laser transmitter with synchronous detection to produce high signal-to-noise ratio (SNR) measurements of CO_2 columns between the aircraft and the surface or tops of clouds. In addition, a pseudorandom-noise (PRN) transmitter and receiver are part of the overall system

to measure the range from aircraft to the backscattering surface. This multifrequency fiber laser lidar (MFLL) was built by ITT Exelis Geospatial Systems as a prototype of a laser system to be flown in a future space mission for global CO_2 measurements.

The MFLL transmitter produces three simultaneous laser wavelengths with different IM frequencies (one on the CO_2 absorption line and two off the line on opposite sides) with a combined average power of 5 W. Since all LAS beams are also transmitted simultaneously, they have 100% spatial and temporal overlap, eliminating sensitivity to regions of highly varying surface reflectance and minimizing effects of atmospheric turbulence by making them common mode terms. The PRN altimeter also has an average power of 5 W. The reflected signals from the surface or cloud tops for both the LAS

Figure 5 Cross-section of water vapor mixing ratios measured by the DLR DIAL system onboard the DLR Falcon aircraft on 12 November 1998 across a tropopause fold region. Tropopause is the boundary between the troposphere and stratosphere, and it was generally located near the blue-green border in this figure. Reproduced from Ehret, G., Hoinka, K., Stein, J., Fix, A., Kiemle, C., Poberaj, G., 1999. Low stratospheric water vapor measured by an airborne DIAL. *Journal of Geophysical Research* 104, D24. <http://dx.doi.org/10.1029/1999JD900959>.

and PRN altimeter are collected by the same telescope. The LAS and PRN altimeter returns are optically separated and detected by separate low-noise detectors. The energy-normalized LAS return signals are ratioed to yield the differential transmission of the transmitted wavelengths, and the natural log of the differential transmission is directly proportional to the CO₂ column amount. The PRN altimeter return is analyzed to determine the range to the surface or cloud, and provides information on the relative intervening aerosol-scattering profile and surface reflectance.

The MFL system has been extensively evaluated in many flight test campaigns conducted both during the day and at night, over a wide range of surface conditions (land and water), and in clear and scattered-cloud conditions. An example of the MFL measurements of surface reflectance and CO₂ columns (shown in terms of equivalent CO₂ mixing ratios) is shown in [Figure 6](#). *In situ* CO₂ profiles were obtained by a UC-12 (red) and Cessna (blue) aircraft for comparison with the remote MFL CO₂ measurements. The 1 s average surface reflectance variations obtained from the off-line backscatter returns are shown along the flight leg. The reflectance varied by a factor of 2.5 over very short distances as the laser beam backscattered from different surface types. This would create large errors in the IPDA CO₂ measurement unless the beams are transmitted simultaneously and the reflectance divides out in the IPDA analysis. The SNR for the MFL CO₂ measurement was found to be 760 for 1 s average (0.6 ppmv) and over 2000 for 10 s average (0.2 ppmv), which both exceed the CO₂ column measurement precision identified by the National Research Council (NRC) for the active sensing of CO₂ emissions over night, days, and seasons (ASCENDS) mission.

Other airborne lidar systems for IPDA CO₂ column measurements are under development and flight testing, and they include narrow and broadband-pulsed lidar systems

operating in the 1.57 and 2.06 μm regions and a heterodyne CW LAS system operating in the 2.06 μm region.

Recent DIAL System Studies and Developments

The idea of putting DIAL systems in space has been discussed since the late 1970s, and the initial emphasis was on the measurement of H₂O and O₃. This possibility became more likely with the successful deployment of the first cloud and aerosol lidar system on the space shuttle, the Lidar In-space Technology Experiment (LITE), in 1994 and the Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation (CALIPSO) mission launched in 2006. The rationale for putting DIAL systems in space is to provide high-vertical-resolution measurements of gases such as O₃ and H₂O (along with aerosol and cloud measurements) across the troposphere, and of O₃ and aerosols across the stratosphere. Achieving total column CO₂ at high spatial resolution from space using laser remote sensing was considered to be of high priority for climate studies by the 2007 NRC decadal survey study. This study identified the ASCENDS space mission as being capable of providing global-scale CO₂ mixing ratio measurements by day and night, over all latitudes and seasons. Several approaches are being investigated for development of a CO₂ and O₂ space-based lidar system to achieve this capability.

Global O₃ Measurements

A number of key global atmospheric science issues can be addressed by a space-based O₃ DIAL system, including photochemical O₃ production, destruction, and transport in the troposphere; stratosphere-troposphere exchange; and

Figure 6 MFL measurements made on 31 July 2009 over the US Department of Energy's (DOE) Atmospheric Radiation Measurement (ARM) site in Lamont, Oklahoma. Flight track and altitude (top left), *in situ* CO₂ profiles (top right), relative surface backscattering (off-line wavelength) (middle), and MFL CO₂ column measurements with 1 s averaging along the flight track (bottom) are shown.

stratospheric O₃ depletion and dynamics. High-vertical-resolution (2–3 km) tropospheric O₃ measurements from space are needed for most of these studies, and this capability is not available from current or planned passive remote-sensing satellites.

Figure 3 shows an example of the type of latitudinal O₃ cross-section that could be provided in one pass of a space-based O₃ DIAL system. Even with the DIAL system optimized for tropospheric O₃ measurements (see the system description in Table 1), it would also provide simultaneous high-resolution stratospheric measurements of O₃ (1 km vertical, 100 km horizontal) and aerosols (100 m vertical, 10 km horizontal). In addition, these DIAL measurements will be useful in assisting in the interpretation of passive, remote-sensing measurements and in helping to improve their data-processing algorithms.

Figure 7 shows a simulation for expected measurement uncertainties as a function of altitude for an O₃ DIAL system at an orbital altitude of 400 km for the lidar parameters given in Table 5 using the US Standard Midlatitude O₃ model. In the middle of the stratosphere, where O₃ number densities are highest, the measurement uncertainty is a minimum of about 2%. In the troposphere, it increases to about 10% for altitudes below 6 km, which is similar to the performance of the airborne UV DIAL system.

Measurement of O₃ from space with the DIAL technique requires the development of high-power (>5 W) tunable lasers in the UV and large collection area (>3 m²) receivers. Current technology advancements have led to the development of low-pulse-energy (~5 mJ), moderate-power (~1 W), tunable solid-state lasers. As an interim step to space, these lasers have been incorporated into a compact (72 × 57 × 49 cm) DIAL system called the Global Ozone Lidar Demonstrator (GOLD) for autonomous operation on a Global Hawk uninhabited aerial system (UAS) aircraft. The packaging of the GOLD system is illustrated in Figure 8. With a nominal vertical measurement resolution of about 300 m and a horizontal averaging distance of 40 km, an O₃ measurement accuracy of better than 10% is expected. GOLD is planned to serve as a demonstrator of a space-based DIAL system and for use in field experiments to acquire long-range long-duration measurements from Global Hawk and for validation of O₃ measurements from the Thermal Emission Spectrometer (TES) and other passive satellite instruments.

Global H₂O Measurements

H₂O and O₃ are important to the formation of OH in the troposphere, and OH is at the center of most of the chemical reactions in the lower atmosphere. In addition to influencing

Figure 7 Simulations of expected space-based O_3 DIAL performance using the parameters given in Table 4 and nighttime and daytime background conditions.

Table 5 Example system parameters and performance goals for space-based O_3 and H_2O DIAL and CO_2 IPDA measurements from low Earth orbit (<400 km)

Detector quantum efficiency (QE) (%)	31	60	Various

the production of OH, H_2O is an excellent tracer of vertical and horizontal transport of air masses in the troposphere, and it can be used as a tracer of stratosphere–troposphere exchange. Increased aerosol sizes due to high relative humidity can also affect heterogeneous chemical processes in the boundary layer and in cloud layers. Thus, knowledge of H_2O distributions can be used in several different ways to understand better the chemical and transport processes that influence the composition of the global troposphere.

The combination of active and passive measurements can provide significant benefits for H_2O , temperature, aerosol, and cloud information. High-vertical resolution H_2O (≤ 1 km), aerosol (≤ 100 m), and cloud top (≤ 50 m) measurements from the lidar along the satellite ground track can be combined with the horizontally contiguous data from nadir passive sounders like a Fourier transform spectrometer

(FTS) to generate a more complete high-resolution H_2O , aerosol, and cloud field for use in the various studies indicated in this article. The Combined Active and Passive Environmental Sounder (CAPES) concept of the combination of DIAL and FTS measurements is shown in Figure 9. The high-vertical H_2O distribution information provided by the DIAL system will assist in improvements in the retrieval of temperature (T) profiles and H_2O distributions from FTS data. In addition, the combination of T from the FTS and the improved H_2O field can be used to derive a more accurate 3D relative humidity field. Simultaneous aerosol and cloud profiling by the DIAL system will further enhance the strong synergism with aerosol and cloud mapping by other active and passive instruments like those in the A-train orbit for missions addressing atmospheric chemistry, radiation, hydrology, natural hazards, and meteorology.

Figure 8 Schematic diagram of the packaging of the GOLD system for installation on the Global Hawk aircraft. Figure courtesy of Hair, J., NASA Langley.

The technology for a space-based H₂O DIAL system is developing incrementally in the areas of high-efficiency, high-energy, high-spectral-purity, long-life lasers with tunability in the 940 nm region; low-weight, large-area, high-throughput, high-background-rejection receivers; and high-quantum-efficiency, low-noise, photon-counting detectors. Figure 10 shows simulations of random errors for a space-based 940 nm H₂O DIAL system at 400 km using the parameters given in

Table 5. The simulation uses several lines in the 940 nm region that are chosen for their different absorption cross-sections and low temperature dependence. In the altitude range, where each cross-section is most sensitive, the random error is less than 5%. Thus, using two or three interleaved lines, the entire altitude range from near the surface to above 8 km can be covered to better than 10% accuracy. The European Space Agency (ESA) has conducted a system study for the development of a H₂O DIAL system from space called Water Vapor Lidar Experiment in Space (WALES). Achieving high pulse energy and high-power lasers for space-based H₂O DIAL applications remains the critical element in the development of H₂O DIAL systems for space.

Global CO₂ Measurements

The US National Research Council's report, entitled *Earth Science and Applications from Space: National Imperatives for the Next Decade and Beyond*, identified the need for a near-term space mission of ASCENDS. The primary objective of the ASCENDS mission is to make CO₂ column measurements across the troposphere during the day and night over all latitudes and all seasons, and in the presence of scattered clouds. These measurements would be used to reduce significantly the uncertainties in global estimates of CO₂ sources and sinks, to provide an increased understanding of the connection between climate and CO₂ exchange, to improve climate models, and to close the carbon budget for improved forecasting and policy decisions. To meet the science objectives of understanding carbon cycle processes, a CO₂ mixing ratio (XCO₂) measurement precision of about 1 ppmv over an atmospheric column

Figure 9 The concept of the combination of space-based DIAL and FTS measurements is illustrated in this figure. High-vertical resolution from DIAL is combined with large spatial coverage provided by FTS to enhance the quality of measurements.

Figure 10 Simulations of expected space-based H₂O DIAL performance using the parameters in Table 5 and nighttime background conditions. Any altitude region of the troposphere can be probed by the choice of an appropriate H₂O absorption cross-section using the electronically tunable laser.

weighted across the troposphere is needed. This represents a combined CO₂ and O₂ column measurement uncertainty of about 0.3% for XCO₂. This is a very challenging requirement, and in addition to the airborne lidar systems mentioned in this article for CO₂ column measurements, there are two lidar systems being flight-tested for the O₂ column measurements: an IM-CW O₂ lidar system operating in the 1.26 μm region, which is being incorporated into the previously described MFL CO₂ lidar system, and a pulsed O₂ lidar system operating in the 0.765 μm region, which is being combined with the pulsed 1.57 μm CO₂ lidar system. These O₂ lidars operate using surface and cloud backscattering in an IPDA measurement of the O₂ column, which is then divided into the CO₂ column to derive XCO₂. Other techniques to obtain high-precision (≤ 1 hPa) estimates of the dry atmospheric density from meteorological analyses are also under evaluation. While airborne DIAL and IPDA systems continue to make significant contributions to our understanding of O₃, H₂O, CO₂, aerosol, and cloud distributions in investigations of atmospheric chemistry, dynamics, meteorology, and climate processes, they cannot provide the global and temporal coverage that a space-based DIAL and IPDA system can. Significant progress has been made in identifying the system requirements and enabling technologies needed for space-based DIAL and IPDA systems, and progress is being made in their development (see Table 5). Within the next decade, it is expected that DIAL and IPDA systems will be deployed in space for global measurements of CO₂ and CH₄, which use IPDA in the 1.65 μm region, and possibly H₂O and O₃.

Introduction

The Doppler effect, in which radiation scattered or emitted from a moving object is shifted in frequency owing to the movement of the object, can be utilized by specially designed lidar systems to measure atmospheric motions, including winds. Atmospheric Doppler lidars operate by irradiating a volume of atmosphere with a pulse of very narrowband, laser-produced radiation, then detecting the change in frequency of the radiation backscattered from atmospheric aerosol particles or molecules present in the volume. The technique is directly analogous to that employed in Doppler weather radars, except that lidar wavelengths are three to four orders of magnitude shorter, which leads to some important differences between radar and lidar characteristics. Because radiation at wavelengths in the optical region of the spectrum is efficiently scattered by aerosols and molecules, Doppler lidars do not require the presence of hydrometeors or insects to obtain useful results. Optical radiation can be tightly focused, virtually eliminating ground clutter and enabling lidar probing of volumes to within a few meters of terrain or structures. However, because optical radiation is severely attenuated by cloud water droplets and fog, Doppler lidars do not typically probe into or beyond most atmospheric clouds – the one exception being tenuous ice clouds such as cirrus, which often are characterized by low optical extinction and high backscatter, making them excellent lidar targets.

The characteristics of Doppler lidar make the technique well suited to making detailed measurement of wind flows for a wide variety of applications. Lidar beams can easily be scanned to characterize motions within very confined three-dimensional spaces such as shallow atmospheric boundary layers, narrow canyons, and turbulent structures. Doppler lidar has also been proposed as a satellite-based technique for obtaining global measurements of atmospheric wind fields. By scanning a lidar beam from an orbiting satellite and analyzing backscattered returns from clouds, aerosols, and molecules, a satellite-based instrument could provide important wind information for numerical forecast models.

Basic Principles

The Atmospheric Backscattered Signal

As laser light propagates through the atmosphere, a portion of the incident energy is scattered by the atmospheric molecules and constituents through which the light passes. In lidar applications, the light backscattered (scattered directly back toward the source) is collected and analyzed. The backscattering properties of an atmospheric particle depend on the refractive index, shape, and size of the scattering particle. If the particle is much smaller than the wavelength of the incident radiation, as is the case for laser radiation scattered by

atmospheric molecules, the scattering process is characterized as Rayleigh scattering. In the Rayleigh scattering regime, the energy backscattered by a particle increases proportionally with the inverse of the fourth power of the wavelength. Consequently, Doppler lidar systems designed for molecular scatter can take advantage of significantly increased backscattered signal intensity by operating at short wavelengths. Molecular Doppler lidar systems typically operate in the visible or ultra-violet spectral regions.

Aerosol particles, the other component of the atmosphere that scatters laser light, result in Mie scattering, which is the more generalized scattering case that applies when the diameter of the scatterers is not orders of magnitude smaller than the incident wavelength. Aerosol particles include dust, soot, smoke, and pollen, as well as liquid water and ice. Although in Mie scattering the relationship between the power backscattered by an ensemble of aerosol particles and the incident wavelength is not simply characterized, most studies have shown that Mie backscatter in the atmosphere increases roughly with the first or second power of the inverse of the incident wavelength. In a high aerosol environment, such as in the vicinity of urban areas, an abundance of large particles often results in a roughly linear variation between the inverse of the incident wavelength and the backscattered energy. In more pristine environments, such as the free troposphere, the inverse wavelength/backscatter relationship can approach or exceed a square-law relationship.

The primary objective in Doppler lidar is to measure the Doppler frequency shift of the scattered radiation produced by the movements of the scattering particles. Figure 1 shows

Figure 1 Spectrum of frequencies in a backscattered lidar return, showing unshifted (black) and Doppler shifted (blue) spectra, where the Doppler shift is due to the wind-induced motion of the scatterers. The ratio of aerosol to molecular signal intensity increases with increasing wavelength.

a typical spectrum of the radiation collected at the lidar receiver for a volume of atmosphere irradiated by a monochromatic laser pulse. Molecular scattering produces the broadband distribution in [Figure 1](#), where the broadening results from the Doppler shifts of the radiation backscattered from molecules moving at their thermal velocities. The width of the molecular velocity distribution in the atmosphere ranges from about 320 to 350 m s⁻¹, scaling as the square root of the temperature. In the center of the spectrum is a much narrower peak resulting from scattering of the light by aerosol particles. Since the thermal velocity of the much larger aerosol particles is very low, the width of the distribution of the aerosol return is determined by the range of velocities of particles moved about by small-scale turbulence within the scattering volume. This is typically on the order of a few meters per second. Also shown in [Figure 1](#) is an additional broadband distribution due to scattered solar radiation collected at the receiver. If the laser source is not monochromatic, the backscattered signal spectrum is additionally broadened, with the resulting spectrum being the convolution of the spectrum shown in [Figure 1](#) with the spectrum of the laser pulse. As seen in the figure, the entire spectrum is Doppler-shifted in frequency, relative to the frequency of the laser pulse. The object of a Doppler lidar system is to measure this Doppler shift, given by $\delta f = 2v_{rad}/\lambda$, where v_{rad} is the component of the mean velocity of the particles in the direction of propagation of the lidar pulse and λ is the laser wavelength.

The relative intensity of the scattered aerosol and molecular returns shown in [Figure 1](#) varies considerably as a function of laser wavelength and atmospheric turbidity. For lidar applications, molecular scatter is very strong at ultraviolet lidar wavelengths, decreasing as the fourth power of the wavelength until it is mostly negligible at wavelengths beyond about 1 μ m. Because most aerosol scattering is Mie scatter, which has a much weaker dependence on the laser wavelength, the ratio of molecular to aerosol scattered radiation decreases for longer wavelengths.

Components of a Doppler Lidar

Doppler lidar systems can be designed primarily to measure winds from aerosol-scattered radiation, or from molecule-scattered radiation, or from both. The type of system places specific requirements on the primary components that comprise a Doppler lidar system. A Doppler lidar is typically made up of a laser transmitter to produce pulses of energy that irradiate the atmospheric volume of interest; a receiver that collects the backscattered energy and estimates the backscattered energy and Doppler shift of the return; and a beam-pointing mechanism that directs the transmitter and receiver together in various directions to probe different atmospheric volumes and measure different components of the wind. Whether the primary scatterers are molecules or aerosol particles, in a Doppler system the system design criteria are driven by a fundamental relationship between the error in the estimate of mean frequency shift δf_1 , the bandwidth of the return f_2 , and the number of incident backscattered photons detected N , as in [eqn \[1\]](#).

$$\delta f_1 \propto \frac{f_2}{N^{1/2}} \quad [1]$$

Thus, the precision of the velocity estimate is always enhanced by an increase in the number of detected signal photons and/or a decrease of the bandwidth of the backscattered signal. From the equation, it is obvious that a significantly greater number of photons is required to achieve the same precision in a Doppler measurement from a molecular backscattered signal, characterized by higher bandwidth f_2 , compared to the number required in an aerosol Doppler instrument. The improved measurement precision gained by a narrow-bandwidth return also implies that the transmitter in a Doppler lidar system should be designed for narrow spectral width (typically on the order of the Doppler shift to be measured), and, as in most lidar systems, maximum transmitted energy. The need for a narrowband laser pulse has a strong effect on the laser performance requirements, and usually results in a transmitter that is more complex than the transmitter in a simple aerosol backscatter lidar. Injection seeding, in which a small amount of power from a separate laser is injected into the laser transmitter optical cavity to 'seed' the laser into operating at a single frequency, is used to produce the required narrow-bandwidth laser pulses in Doppler lidar instruments.

The lidar receiver gathers the backscattered photons and extracts the wind velocity as a function of the range to the scattering volume by analyzing the return as a function of time. This requires a telescope, to gather and focus the scattered radiation, and a system element that analyzes the scattered radiation to compute the Doppler shift. The frequency analysis function in a Doppler lidar receiver is carried out using one of two fundamentally different techniques: coherent detection (also known as heterodyne detection) or direct detection (alternatively labeled incoherent detection). The techniques differ fundamentally. In a heterodyne receiver, local oscillator laser radiation is mixed with the backscattered radiation at an optical detector, and the detector output signal is digitized and spectrally processed. A direct detection lidar employs an interferometer to optically analyze the backscattered radiation.

Coherent Doppler Lidar

Description

Coherent or heterodyne lidar is implemented by optically mixing the backscattered laser light with radiation from a continuous-wave, local oscillator (LO) laser whose wavelength is precisely controlled to be equal to, or at a known displacement from, that of the laser transmitter ([Figure 2](#)). The mixing process at the face of an optical detector generates an electrical signal with a frequency equal to the difference frequency between the backscattered signal and the LO laser signal. This signal is typically digitized and processed as a function of time, using digital signal processing techniques, to obtain an estimate of the range-dependent mean frequency shift of the backscattered signal, from which the radial wind component can be derived. A characteristic of coherent lidar is that single pulse returns, even with high signal levels, are characterized by random fluctuations in the backscattered field and the resulting frequency spectrum. Consequently, averaging of multiple pulses usually is employed to increase the accuracy of the mean frequency estimate.

Figure 2 Schematic of coherent detection of backscattered radiation.

The optical mixing process that is fundamental to coherent Doppler lidar provides both benefits and design challenges. Receiver efficiencies (measured as equivalent fraction of incident photons converted to electrons) are quite high, meaning that wind velocities can be estimated from weak backscattered signals. Also, because signal processing is performed on a time-series derived from the mixed signal, receiver bandwidths can be made extremely narrow, effectively eliminating the broadband solar background light as a major source of noise. Thus, unlike that of many lidars, coherent Doppler lidar performance is not degraded under daylight conditions. However, the added photon noise from the local oscillator radiation results in a system noise threshold below which very weak signals cannot practically be extracted, even with substantial multiple-pulse averaging. Because efficient mixing requires phase coherence of the backscattered signal field across the detector, coherent lidar performance at longer ranges can be degraded by strong optical turbulence along the path of the laser pulse. Turbulence effects are more pronounced at shorter wavelengths.

Coherent Doppler lidar systems generally operate in the eye-safe, infrared portion of the spectrum at wavelengths longer than $1.5\ \mu\text{m}$. Currently, the two most common system wavelengths for coherent lidar wind systems are in atmospheric window spectral regions around 2.0 and $10.6\ \mu\text{m}$. Early coherent Doppler lidar measurements, beginning in the 1970s, employed CO_2 laser transmitters and local oscillators operating at wavelengths near $10.6\ \mu\text{m}$. Pulsed CO_2 laser transmitters with as much as $10\ \text{J}$ of energy have since been demonstrated, and systems with $1\ \text{J}$ lasers are still routinely used for atmospheric probing to ranges extending to $30\ \text{km}$ or more. In the late 1980s, solid-state laser transmitters operating near $2\ \mu\text{m}$ wavelengths were introduced into coherent lidar wind-measuring systems. The compact size and potential reliability advantages of solid-state transmitters, in which the transmitter laser is optically pumped by an array of laser diodes, provide advantages over older CO_2 laser technology. Also, because the range resolution obtainable for a given measurement accuracy scales with wavelength, $2\ \mu\text{m}$ instruments are characterized by better range resolution than their $10\ \mu\text{m}$ counterparts, and hence have enhanced ability to probe small-scale features. However, although development of high-energy laser sources operating in the $2\ \mu\text{m}$ region is currently an active research area, lasers with pulse energies greater than

several tens of millijoules have yet to be incorporated into laser systems.

Applications of Coherent Doppler Lidar

Coherent lidars have been employed to measure winds for a variety of applications, and from an assortment of platforms, such as ships and aircraft. Since these lidars operate in the infrared, where aerosol scattering dominates molecular scattering, they require aerosol particles to be present at some level to obtain usable returns. Although clouds also provide excellent lidar targets, most of the more useful applications of coherent lidars have been associated with probing the atmospheric boundary layer or lower troposphere, where aerosol content is highest. One of the special applications of lidar probing is measurement of wind structure and evolution in complex terrain such as mountains and valleys. Over the past 20 years, results of Doppler lidar studies have been used, for example, to characterize the intensity and structure of damaging downslope windstorms in the lee of mountain ranges, advection of pollution by drainage flows in valleys, and formation of mountain leeward turbulence as a potential hazard to landing aircraft. An example of the capability of Doppler lidar to probe complex terrain is shown in Figure 3, in which the advance of a cold front northward during a southerly foehn wind event in the Austrian Alps is clearly indicated. Such measurements are studied to improve understanding of the mechanisms associated with the onset and evolution of severe wind events.

Because coherent Doppler lidars are also well matched to applications associated with probing small-scale, turbulent phenomena, they can be applied to improving aviation safety. Doppler lidars have been deployed in the vicinity of airports to detect and track wing tip vortices generated by arriving or departing aircraft. In the future, a network of ground-based lidars to provide information on vortex location and advection speed could decrease congestion at major airports by increasing landing and takeoff capacity. Also, compact lidar systems deployed on research aircraft have detected wave structures ahead of the aircraft associated with potentially hazardous clear-air turbulence. Doppler lidar installed on the commercial aircraft fleet might be able to look ahead and provide a warning to ensure that passengers have their seat belts fastened before the turbulence is encountered.

Figure 3 Successive lidar vertical plane scans of radial wind speed, showing the progression of a cold front beneath a strong foehn flow in the Austrian Alps. Colors represent radial velocity in m s^{-1} ; distances are in km from the lidar. Courtesy L. Darby, NOAA.

The high resolution obtainable in a scanning lidar can produce informative images of the details of small-scale phenomena. **Figure 4** shows an image of a shallow wave associated with a low-level nocturnal stable layer structure just 50 m above the surface obtained using a scanning $2.02 \mu\text{m}$ Doppler lidar. Similar images taken during different evenings as part of the same experiment illustrated markedly different characteristics, such as much more turbulence along the interface. Such observations enable researchers to improve models and better understand the conditions associated with vertical turbulent transport and mixing of atmospheric constituents such as pollutants.

Direct Detection Doppler Lidar

Description

Direct-detection, or incoherent, Doppler lidar has received significant attention in recent years as an alternative to coherent lidar for atmospheric wind measurements. In contrast to coherent lidar, in which an electrical signal is processed to estimate Doppler shift, an optical interferometer, usually

Figure 4 Wave structure within a nocturnal stable layer at a height of 50 m. Note the stretching of the vertical scale. Courtesy R. Banta, NOAA.

a Fabry–Perot etalon, serves as the principal element in a direct-detection lidar receiver for determining the frequency shift of the backscattered radiation.

One implementation of a direct-detection Doppler lidar receiver is the ‘fringe imaging’ technique. In this design, the interferometer acts as a spectrum analyzer. The backscatter radiation is directed through a Fabry–Perot interferometer, which produces a ring pattern in the focal plane (**Figure 5**). The spectral content information of the incident radiation is contained in the radial distribution of the light. Each ring corresponds to an order of the interferometer and is equivalent to a representation of the backscattered signal frequency spectrum. As the mean frequency of the backscattered radiation changes, the rings move inward or outward from the center. To extract the spectrum of the backscattered light, one or more of the rings are imaged onto a multielement detector, and the resulting pattern is analyzed.

An alternative direct detection receiver configuration employs two interferometers as bandpass filters, with the center wavelengths of respective filters set above and below the laser transmitter wavelength, as shown in **Figure 6**. The incoming radiation is split between the two interferometers, and the wavelength shift is computed by comparing the radiation transmitted by each interferometer. This method, sometimes called the ‘double edge’ technique, has been used to measure winds to heights well into the stratosphere. The major challenge associated with this implementation of a direct detection receiver is optimizing the instrument when both aerosol-scattered and molecular-scattered radiations are present, since in general the change in transmission as a function of velocity is different for the aerosol and molecular signals.

Figure 6 Spectrum of molecular lidar return, showing placement of bandpass filters for a dual-channel (double-edge) direct detection receiver. Courtesy B. Gentry, NASA.

For both types of direct-detection receiver configurations described above, a portion of the radiation incident on the interferometer is reflected out of the system, reducing the overall efficiency of the receiver. Recently, designs that incorporate fiber optics to collect a portion of the reflected radiation and recycle it back into the etalon have been proposed as a way to reduce receiver losses.

Doppler Measurements Based on Molecular Scattering

One of the primary advantages of direct-detection Doppler lidar is the capability for measurements based on scatter from atmospheric molecules. Measurement of Doppler shifts from molecular scattered radiation is challenging because of the large Doppler-broadened bandwidth of the return. Typically, one wants to measure a mean wind velocity with a precision that is much less than the velocity standard deviation of 320 m s^{-1} . This requires a large number of photons. As an example, more than 10^5 photons must be detected to achieve a measurement precision of a few m s^{-1} from molecular-scattered radiation, which typically requires some combination of multiple pulse averaging, powerful lasers, and large receivers for the lidar system.

This need to collect and detect large numbers of photons also means that molecular Doppler measurements are made at

short wavelengths where scatter is strongest. Molecular-scatter wind measurements have been demonstrated in the visible spectral region at 532 nm wavelength and at 355 nm in the near ultraviolet. The ultraviolet region has the dual advantages of enhanced molecular scatter and less-restrictive laser eye-safety restrictions. Figure 7 shows the time series of a wind profile measured throughout the troposphere using a molecular-scatter, ground-based Doppler fringe-imaging lidar operating at 532 nm. The figure also shows measurements from a second receiver channel in which the interferometer design was optimized for the more narrowband aerosol return. For this measurement, returns from 500 pulses, each with 400 mJ of energy, were collected by a 0.5 m receiver aperture and processed.

Heterodyne and Direct-Detection Doppler Trade-Offs

Lively debates within the lidar community have taken place over the past decade regarding the relative merits of heterodyne versus direct-detection Doppler lidars. To a large extent, the instruments are complementary. Generally, heterodyne instruments are quite sensitive for measurements when significant aerosols are present. Processing techniques have been developed that can produce accurate wind measurements rates using only a few lidar pulses, such that several wind observations per second can be obtained. This inherent sensitivity has enabled numerous applications in which a lidar beam has been scanned rapidly over a large volume to obtain time-varying, three-dimensional wind measurements. Heterodyne lidars also operate in the eye-safe infrared portion of the spectrum, which is highly advantageous for general atmospheric research and field studies.

The primary advantage of direct-detection instruments is their demonstrated capability to measure winds from molecular-backscattered returns in the middle and upper troposphere. In pristine air, direct detection offers the only method for long-range wind measurements, even though significant averaging may be required. Direct-detection lidars are also not degraded by atmospheric refractive turbulence. From an engineering perspective, optical system specifications for direct detection systems tend to be somewhat less demanding. For optimum performance, a heterodyne lidar requires a very pure laser pulse and a diffraction-limited receiver field of view that is matched to and precisely aligned

Figure 7 Time-series (in minutes after local midnight) of radial wind speed profiles measured by a fringe-imaging direct detection lidar molecular channel (a) and aerosol channel (b) at Bartlett, NH. Change in wind speed and blocking of the return by clouds are clearly seen. Courtesy P. Hays, Michigan Aerospace Corp.

with the transmitted beam. The requirements for direct detection are more relaxed, such that a somewhat wider bandwidth transmitter and a receiver field of view several times diffraction-limited is sufficient. In direct-detection lidars, the field of view is typically constrained by the need to limit background light for daytime operation. The major design challenge for direct detection instruments is associated with maintaining stability of the Fabry-Perot etalon over a range of temperatures and in high-vibration environments.

Global Wind Measurements

A satellite-based Doppler lidar has frequently been proposed as a way of measuring wind fields over most of the Earth. At present, wind profiles are not well measured from orbiting platforms. Measurement of winds is especially important over regions of the Earth that are not currently well sampled, such as over Northern Hemisphere oceans, as well as over most of the tropics and the Southern Hemisphere. Wind profile information is currently obtained from radiosondes and by tracking cloud and water vapor inhomogeneities using satellite images. Doppler lidar wind measurements could greatly augment the current data set by providing wind estimates throughout the troposphere under clear conditions, and strongly height-resolved observations down to cloud tops when cloud decks are present. Observing system simulation experiments conducted in recent years indicate that satellite-based lidar global wind measurements could lead to a significant improvement in long-term forecast skill if the wind fields can be observed with sufficient accuracy and spatial resolution.

Figure 8 shows an artist's concept of a shuttle-based wind lidar mission. In an operational mission, a satellite carrying the lidar would be placed in a nearly polar orbit. The pulsed laser beam is scanned conically from nadir to obtain different components of the wind velocity. The scanning can be either

Figure 8 Concept for a demonstration wind lidar mission from a shuttle orbiter. In an operational mission, the lidar would be deployed on a polar-orbiting satellite for global coverage. Courtesy M. Kavaya, NASA.

continuous or 'stop and stare.' After sufficient returns are averaged to produce an acceptable estimate, the radial component of the velocity is computed, which would most likely be assimilated directly into numerical forecast models.

Doppler lidar measurement of winds from space is theoretically feasible but technologically difficult. Depending on the orbital height, the scattering volume is anywhere from 450 to about 850 km from the satellite, which challenges the sensitivity of current system types. Because weight and power consumption are critical parameters for space-borne systems, telescope diameter and laser power cannot easily be increased to obtain the necessary sensitivity. Similarly, the ability to average returns from multiple pulses is also limited. The satellite moves at about 7 km s^{-1} ; therefore, in order to obtain measurements over a horizontal distance of 300 km (the resolution of the radiosonde network), only about 45 s are available to make observations from the multiple look angles needed for a useful measurement. It should be also noted that, as a result of the high orbital velocity of the satellite, the precision and knowledge of beam pointing is extremely critical for measurements from satellites. For a lidar operating with a nadir angle of 45° , an error in the pointing knowledge of just 1 mrad results in an error of about 5 m s^{-1} introduced into the measured radial component of the wind by the satellite motion.

Despite the challenge of employing a Doppler lidar for satellite-based wind measurements, efforts are continuing to develop the appropriate technology and to assess the impact of the observations. The European Space Agency is planning a Doppler wind lidar demonstration mission for the late 2000s that would incorporate a nonscanning, direct-detection instrument. Doppler lidar technology research and simulation experiments aimed at satellite-based wind sensing continue at several research centers within the United States, Europe, and Japan.

Introduction

Optical techniques for remote sensing of the atmosphere have existed for many decades. In the 1930s, Hulburt used mechanically chopped searchlights as an optical source and a telescope as the receiver to measure atmospheric signals to 28 km. In the 1950s, Elterman used the same searchlight technique to derive atmospheric temperature to altitudes in excess of 60 km. Theodore Maiman's invention of the laser in 1960 created a new optical source, enabling the development of lidar and revolutionizing the field of remote sensing.

Lidar stands for *light detection and ranging*, and is used to describe the use of laser radiation to make remote measurements of the atmosphere, ocean, or hard target where the backscattered signal is collected by use of a telescope. Some significant early achievements are summarized in Table 1. Following these early efforts, researchers soon broadened the range of phenomena used for laser remote sensing by using the Raman effect to study molecular species remotely. Raman lidar technology can be used to provide scientifically meaningful measurements of a wide variety of atmospheric quantities including temperature, ozone and aerosol size. The presentation here will focus on the use of Raman lidar in the measurements of water vapor, aerosols, and cirrus clouds.

Raman Scattering

In 1921, Chandrasekhara V. Raman and his students began investigating the light scattering properties of various substances. Their experiments were carried out at the University of Calcutta in India, where Raman held an endowed chair in physics. These investigations led to the discovery of a very weak type of secondary light that is generated at wavelengths shifted from the incident wavelength. Initially they used filtered sunlight as the source and the shifted wavelengths

were observed by eye. Raman soon realized that they were observing a completely new scattering phenomenon of fundamental importance. They found that the frequency shifts, their relative intensities, and the state of polarization were independent of the exciting radiation. The frequency shifts observed were attributed to the frequencies of oscillation of the atomic bonds in a molecule. Raman was awarded the Nobel Prize for his work in 1930.

A quantum mechanical description of the Raman scattering process (Stokes shift) involves a transition from an initial state of energy E_i to an intermediate state, known as a virtual state, prior to the transition to the final state E_f . This is shown in the Figure 1 where both Stokes and anti-Stokes Raman scattering are shown. After a Stokes scattering event, the system is left in a higher energy state so that the scattered photon is of longer wavelength (lower energy) than the incident photon. In anti-Stokes scattering, the final energy state is lower than the initial state.

The Raman Lidar Technique

The Raman lidar technique entails measuring the rotational or vibrational-rotational component of Raman scattering from the atmosphere. This approach has proven to be a highly versatile one permitting a wide variety of atmospheric studies to be performed. Water vapor, nitrogen, and oxygen are molecules of interest in the normal atmosphere that exhibit convenient vibrational Raman shifts. These shifts are approximately 3657, 2331, and 1556 cm^{-1} , respectively. A spectrum of Raman scattering (Stokes shift) from the normal atmosphere is shown in Figure 2.

The Standard Raman Lidar Equation

The standard single scattering Raman lidar equation can be expressed as in eqn [1].

Table 1 Early developments in the history of lidar

Event	Date	Researchers	Comments
Laser invented	1960	Maiman	
First laser remote sensing measurements – echos from the moon	1962	Smullin and Fiocco	
Invention of the Q-switch	1962	McClung and Hellwarth	Permitted much higher power levels making atmospheric measurements feasible
First atmospheric laser remote sensing measurements	1963	Fiocco and Smullin	First atmospheric lidar measurements closely followed the invention of the Q-switch
First differential absorption lidar (DIAL) measurements of water vapor	1966	Schotland	DIAL measurements of atmospheric water vapor preceded Raman lidar measurements of water vapor
First measurement of the atmospheric sodium layer using resonance lidar	1968	Bowman <i>et al.</i>	

Figure 1 Schematic diagrams of both Stokes and anti-Stokes Raman scattering. Stokes scattering is the predominant phenomenon observed in the atmosphere. This results in a scattered photon of lower energy and thus longer wavelength than the incident. Anti-Stokes scattering results in a higher energy or shorter wavelength photon being scattered.

Figure 2 Measured spectrum of Raman-shifted and unshifted backscatters from the normal atmosphere. Redrawn with permission from Ianaba and Kobayashi (1972).

$$P(\lambda_{X,r}) = \frac{O_X(r)P_0(\lambda_L)N_X(r)[d\sigma_X(\lambda_L, \pi)/d\Omega]A\xi(\lambda_X)}{r^2} \times \exp\left\{-\int_0^r [\alpha(\lambda_L, r') + \alpha(\lambda_X, r')]dr'\right\} \quad [1]$$

Here $P(\lambda_{X,r})$ is the background subtracted power received at the Raman-shifted wavelength appropriate for molecular species X as a function of range, r . $O_X(r)$ is the channel overlap function, and $P_0(\lambda_L)$ is the output power of the laser at the laser wavelength, λ_L . $N_X(r)$ is the number density of molecules and $d\sigma_X(\lambda_L, \pi)/d\Omega$ is the Raman differential backscatter cross-section at the laser wavelength. $\xi(\lambda_X)$ is the

total lidar receiver optical efficiency at the wavelength of the Raman species of interest and includes factors such as the reflectivity of the telescope, the transmission of any conditioning optics, the transmission of any filters, and the quantum efficiency of the detector. A is the receiver telescope area. The exponential factor gives the two-way atmospheric transmission, where $\alpha(\lambda_X, r)$ is the total extinction coefficient due to scattering and absorption by molecules and aerosols at the Raman-shifted wavelength as a function of range along the path of the laser beam. In this context, the term 'aerosols' may be used to describe any nonmolecular atmospheric constituent such as dust,

water droplets, ice crystals, etc. This equation uses the simplifying assumption that the Raman scattered signals are monochromatic.

The Raman effect has been used to great effect in laboratory studies of various materials. Since the advent of the laser, it has also been used for atmospheric studies. Table 2 presents a chronological list of various milestones in the history of Raman lidar measurement capability. As an illustration of the Raman lidar technique for measuring water vapor, aerosols, and clouds, the measurement capability of a single Raman lidar system will now be illustrated.

The NASA/GSFC Scanning Raman Lidar

The NASA/GSFC scanning Raman lidar (SRL) is housed in a single mobile trailer and contains a 0.76 m telescope, two lasers (XeF excimer (351 nm) and a tripled Nd:YAG (355 nm)), various wavelength-selection optics and combined photon counting and analog data acquisition electronics. The trailer also provides laboratory space for new experiment development as well as workspace for up to three analysts. The system

is designed to measure the Raman scattering from water vapor, liquid water, nitrogen, and oxygen. In addition, the Rayleigh–Mie signal is measured as well. A large mirror enables full aperture scanning within a single plane perpendicular to the trailer axis. The scanning capability is used to assess horizontal variability of various constituents as well as to improve the retrieval of scientific quantities in the lowest part of the atmosphere. The data are typically acquired with 1 min temporal resolution and 7.5 m vertical resolution. Some of the basic measurement capabilities of this system will now be illustrated.

Measurements

Water vapor

The water vapor mixing ratio is defined as the ratio of the mass of water vapor to the mass of dry air in a given volume. The mixing ratio is conserved in atmospheric processes that do not involve condensation or evaporation, and thus serves well as a tracer of the movement of air parcels in the atmosphere. It can be calculated from a ratio of Raman lidar signals for water vapor and nitrogen using eqn [1] above.

Table 2 History of atmospheric measurements using Raman Lidar

<i>Event</i>	<i>Measurement date</i>	<i>Publication date</i>	<i>Researchers</i>	<i>Comments</i>
Earliest claimed measurement of Raman scattering (nitrogen) from the atmosphere	1966	1968	Cooney	
Measurement of Raman scattering from oxygen and nitrogen	1967	1967	Leonard	Definitive evidence of measurements provided by photographs of oscilloscope traces

During April 1994, the SRL participated in the first intensive field campaign sponsored by the US Department of Energy's Atmospheric Radiation Measurements (ARM) program at their northern Oklahoma Cloud and Radiation Testbed site. The SRL was operated for approximately 9 h on the night of 21 April during this field campaign. Figure 3 shows the SRL water vapor mixing ratio measurements (1 min summation of lidar data) compared with a radiosonde measurement made at 0535 UTC. The agreement is excellent. The figure indicates that the atmosphere was relatively well mixed up to an altitude of approximately 2 km. Above this altitude there was abrupt drying. Cirrus clouds were present during the entire evening as well.

A color image of water vapor evolution can be created by combining the vertical lidar profiles into a time–height image. The result is shown in Figure 4. This image reveals that the water vapor field showed variations in the regions below 2 km throughout the night. Furthermore, the dry slot located just above this mixed layer generally rose in altitude during the night from approximately 2.2 km at 0230 UTC to 2.7 km at 1100 UTC. Above the dry slot, the atmosphere was quite stable throughout the night.

Aerosols

The corresponding aerosol scattering ratio image from the night of 21 April 1994 is shown in Figure 5. The aerosol scattering ratio is used to quantify the ratio of aerosol to molecular scattering. It is defined as the ratio of the volume backscatter coefficients for total (molecular+aerosol) scattering to pure molecular scattering. The vertical scale has been expanded to 15 km in altitude, allowing the evolution of aerosols at all levels of the troposphere to be studied. In the aerosol field, the dry slot that was revealed in the water vapor field is seen as a decrease in the scattering ratio indicative of reduced aerosol loading. A comparison of the water vapor and aerosol images would tend to indicate that below a mixing ratio value of approximately 6.5 g kg^{-1} the aerosol scattering ratio was less than approximately 1.05. This creates the apparent increase in the dry slot at 0800 UTC as revealed in the aerosol scattering ratio image. Cirrus clouds formed in the upper troposphere on this night as well. The evolution of cirrus cloud structure can be studied over the course of the night using Raman lidar imagery as shown here. The bases of the cirrus clouds were as low as 9 km while the tops

Figure 3 Comparison of Raman lidar measurement of water vapor mixing ratio and radiosonde. Measurements occurred 21 April 1994 at the DOE ARM CART site in northern Oklahoma. A 1-min summation of lidar data was used.

Figure 4 Color image of water vapor mixing ratio showing the evolution of water vapor in the troposphere. A thin, persistent dry slot rose in altitude during the night.

rose to approximately 12.5 km. As will be shown later the cirrus cloud optical depth can also be quantified using Raman lidar.

By analyzing the slope of the Raman nitrogen or oxygen signal, the extinction due to aerosols can be quantified. Aerosol optical depth can be obtained by integrating aerosol extinction with range. The Raman lidar is able to simultaneously quantify aerosol extinction and aerosol backscattering in the same atmospheric volume. When these quantities are studied along with the relative humidity (calculated from the Raman lidar water vapor mixing ratio using a temperature profile obtained from radiosonde), changes in aerosol optical properties due to hygroscopic growth of the aerosol particles can be studied. For example, **Figure 6** shows four simultaneously acquired images of water vapor mixing ratio, relative humidity, aerosol backscattering coefficient, and aerosol extinction.

The ratio of extinction to backscattering can be used to quantify aerosol growth versus relative humidity. A relative humidity value of 70% is generally taken to be the level above which aerosols can begin swelling. This can be revealed by the ratio of extinction to backscattering which will tend to increase as the aerosol grows in size.

Daytime Water Vapor

The Scanning Raman Lidar was deployed to the panhandle of Oklahoma in the United States for the first International H₂O Project held in May–June, 2002. Prior to the deployment, the SRL received technology upgrades to improve measurements of water vapor during the daytime where high solar

Figure 5 Color image of aerosol scattering ratio depicting the evolution of aerosol structure throughout the troposphere. Cirrus clouds were present during the night between the altitudes of 9 and 12.5 km. The dry region in the water vapor image is seen again here as a region of low aerosol scattering.

background makes measurement of the weak Raman signals more difficult than at night. In **Figure 7** is shown the water vapor image acquired on May 22, 2002 during a dryline event near the lidar site. This image is displayed with 3 min temporal and between 100 and 300 m vertical resolution and reveals convective plume structures in the boundary layer, which is seen to increase in height as the day progresses. Approximately 1 hour before sunset, which occurred at 0200 UT (shown as 26 in the image), the dryline became better defined resulting in a significant drying above ~1.5 km and increased moisture below.

Upper Tropospheric Water Vapor

Small errors in the quantification of water vapor at high altitudes can create large errors in radiative transfer calculations. Therefore ground-based monitoring of upper tropospheric water vapor is important in climate change studies. The same hardware upgrades to the SRL that permitted the improved daytime measurements of water vapor shown in **Figure 7** also permitted very high-quality upper tropospheric retrievals of water vapor during the nighttime. In **Figure 8** is shown a comparison of a 30-min summation of SRL water vapor mixing ratio data and a radiosonde measurement on the night of 5 December 2000. Excellent agreement is seen between the two sensors on this particular occasion, although radiosondes

Figure 6 Four-panel display of the water vapor mixing ratio, relative humidity, aerosol backscattering ratio, and aerosol extinction. The bottom 5 km of the atmosphere is displayed so that changes in boundary aerosol properties can be revealed. Simultaneous studies of these parameters can reveal information about the growth of aerosols as a function of relative humidity.

can have difficulty quantifying the very small amounts of water vapor present in the cold upper troposphere.

Cirrus Cloud Optical Depth Measurements and Influence on Satellite Radiances

The Scanning Raman Lidar was deployed to Andros Island, Bahamas during August and September 1998 for the third Convection and Moisture Experiment (CAMEX-3). CAMEX-3 was a multi-instrument field campaign designed to improve hurricane tracking and intensification forecasting. During the period of August 21–25, hurricane Bonnie passed near Andros Island and influenced both the water vapor and the cirrus cloud environment. The SRL measurements of cirrus cloud acquired on August 23 indicated that the cirrus optical depths ranged from a high of ~ 0.7 to a low of ~ 0.005 . This range of optical depths provided a convenient dataset to test the sensitivity of satellite retrievals of precipitable water vapor to the presence of cirrus clouds.

In [Figure 9](#) are shown the SRL measurements of total atmospheric precipitable water and cirrus cloud optical depth from August 23 along with the corresponding GOES-8 (Geostationary Observational Environmental Satellite)

precipitable water retrievals. The lidar measurements indicate that the total precipitable water (TPW) changed relatively little during the measurement period. All significant variation in the retrieved TPW from GOES is attributed to the influence of cirrus. There is a strong correlation between cirrus cloud optical depth and the GOES-derived TPW. Furthermore, the GOES and lidar TPW measurements converge at the end of the data record where optical depths are very low as expected.

It is clear from [Figure 9](#) that increases in cirrus optical depth elevate the retrieved TPW. These results indicate that satellite radiances are noticeably affected for cirrus optical depths above approximately 0.005. Undetected cirrus cloud will create a consistent high bias in GOES satellite retrievals of TPW. Using the cirrus cloud detection criteria of the most recent International Satellite Cloud Climatology Project analysis indicates this bias will be up to 20% for cirrus clouds measured over water and 40% for cirrus clouds measured over land. It is apparent from the results presented here that satellite retrieval algorithms need to be able to detect the presence of cirrus clouds with IR optical depths as small as 0.005 in order to avoid significant influences on satellite radiances and thus potential errors in retrievals.

Figure 7 Water vapor mixing ratio measurements acquired on May 22, 2002 during the passage of a dryline near the SRL location in western Oklahoma. The boundary layer depth is seen to increase until ~2400 UT at which time the dryline influence became more noticeable. Sunset on this day was ~0200 UT (shown as 26 UT). The white stripes at for example 24 UT and 3.2 km are due to attenuation of the laser beam by clouds.

Future Developments: Airborne Raman Water Vapor Lidar

Despite the great success of Raman lidar technology for both daytime and nighttime measurements of water vapor from ground-based platforms, Raman lidar measurements from aircraft are very limited. No airborne Raman lidar system has been constructed to measure water vapor during both daytime and nighttime. To address this deficiency, the performance of an airborne Raman water vapor lidar was studied as a part of the NASA Instrument Incubator Program. A numerical Raman lidar model was constructed and used to study the anticipated measurements of this new system for water vapor conditions ranging from subtropical to arctic. The results demonstrate that a significant performance increase is realized by operating a Raman lidar looking downward from an aircraft compared to that same system looking upward from the ground. The lidar system simulated was based on a 15 W tripled Nd:YAG laser and a 0.6 m telescope. The optical field of view of the telescope is 0.25 mrad and the spectral widths of the water vapor and nitrogen interference filters are both 0.3 nm. In Figure 10 are shown the simulated profiles of water vapor mixing ratio measured by this airborne Raman lidar under both nighttime (A) and daytime (B) conditions for subtropical conditions during August (the radiosonde profile used was from Andros

Figure 8 Nighttime profile of SRL water vapor mixing ratio and radiosonde measurement plotted to 14 km using a 30-min summation of lidar data. Upper tropospheric water vapor is very important in atmospheric radiation studies. The Raman lidar can provide long-term ground-based monitoring of this important quantity.

Island, Bahamas on 22 August 1998). The nighttime simulations used a 10 s summation while during the daytime the summation was 3 min. The daytime simulations assume a 0° solar zenith angle over water. The vertical smoothing applied to the profiles is as follows: For the nighttime case,

Figure 9 Cirrus optical depth-line profile.

Figure 10 Simulations of the nighttime (a) and daytime (b) water vapor measurement performance of an airborne Raman lidar. A subtropical water vapor profile was assumed and the daytime simulations used a 0° solar zenith angle over a water surface. These simulations reveal that an airborne Raman lidar can provide high-quality water vapor measurements using as little as 10 s of integration time during the nighttime and typically 3 min during the daytime.

between the altitudes of 0–4 km, a 200 m smoothing is used, between 4 and 7 km, the smoothing is 120 m, and above 7 km, the smoothing is 40 m. The random error in the retrieval is less than 10% up to 9 km and closer to 5% in the very moist region near the surface. For the daytime case, the data are smoothed to 200 m for all altitudes. The modeled error is generally less than 5% except in the region between 5 and 6 km, where it is closer to 7%. In the lowest 2 km of the profile, the error is 3–4%. These profiles demonstrate that an airborne Raman lidar of the specifications modeled here would be capable of very high-quality profiles of water vapor under both daytime and nighttime conditions. Such a system would indicate a significant advance in airborne remote sensing since the additional Raman measurements that have been described here could be made simultaneously with the water vapor mixing ratio.

Summary and Conclusions

Raman Lidar technology has been used to measure a broad range of atmospheric phenomena including water vapor, cloud liquid water, water temperature, atmospheric density and temperature, aerosol backscattering and extinction, stratospheric ozone, and pollutants. Systems have been constructed with the ability to measure many of these parameters simultaneously. This ability to make numerous simultaneous lidar measurements is quite unique to the Raman technique due to the spectral shifting of the return signals. This has permitted the construction of systems such as the NASA/GSFC Scanning Raman lidar, which is capable of precise tropospheric measurements of water vapor along with measurements of aerosols and cirrus clouds. Liquid water

measurements are also possible simultaneously with those of water vapor and aerosols.

Raman lidar has a further attractive feature in its relative simplicity compared to competing techniques such as differential absorption lidar. This has permitted an automated Raman lidar to be developed by the Department of Energy. This system provides continuous automated measurements of water vapor and aerosols at the northern Oklahoma Cloud and Radiation Testbed Site. With improvements in technology, we can expect the future to bring several advances in Raman lidar technology and corresponding advances in atmospheric measurements. These include: (1) higher performance systems for ground-based research; (2) lower cost automated systems for precise characterization of the atmospheric state over extended periods; and (3) airborne systems combining water vapor, liquid water, aerosol scattering, extinction, and depolarization. Such systems and new analysis techniques should permit Raman lidar to remain one of the most powerful remote sensing techniques being applied to atmospheric studies.

Acknowledgements

Support from NASA and the Department of Energy in the development and scientific application of the Scanning Raman Lidar is gratefully acknowledged. In addition I would like to express my appreciation to all members of the Raman lidar group at NASA/GSFC for their efforts over the years.

Synopsis

This article summarizes the principles and practices of the resonance lidar techniques used to measure constituents, temperatures, and winds in the middle and upper atmosphere (~70–150 km). The lidar equation is presented with a resonance solution that highlights the robustness of the technique due to the complete quantum mechanical description of scattering by atoms and molecules. The technique is illustrated with contemporary examples of high-resolution (~100 m, 1 min) measurements of mesospheric metals, temperatures, and winds. These measurements allow estimation of the constituent, heat, and momentum fluxes that are crucial for understanding nonlinear coupling and transport.

Lidar technologies, the optical counterpart to radar, have been especially important for studying the middle atmosphere from the middle stratosphere (from about 30 km altitude) to the lower thermosphere (to about 110 km altitude). This region is inaccessible to *in situ* probing from aircraft, balloons, and satellites. Only rocket probes and remote-sensing instruments can be used to measure the atmospheric composition and structure at these high altitudes. Lidars typically employ high-energy pulsed lasers, large optical telescopes, and range-gated photon counting detectors to derive atmospheric profiles. There are two primary types of lidar systems that are being used to probe the middle atmosphere. Rayleigh/aerosol systems employ backscattering from air molecules and ice particles to measure temperature, wind, and aerosol profiles up to about 80 km altitude. Resonance fluorescence lidars employ resonant backscattering from the atomic metal layers (i.e., Na, Fe, K, Ca, Ca⁺, and Li) and from the hydroxyl (OH) layer. These layers are usually found in the upper mesosphere and lower thermosphere in the 70–110 km altitude range, though recent observations have revealed events where Fe extends to 155 km. The metal layers are the product of meteor ablation while the OH layer is formed by chemical processes.

Because of its relatively high abundance, large resonant backscatter cross-section, and visible wavelength, Na has been the most widely studied species. In fact, the first metal resonance lidar measurements were made in 1968 just 2 years after the invention of the tunable dye laser. Existing systems based upon Na provide the highest resolution and most accurate wind and temperature measurements. However, rugged K and Fe systems have also been developed to make upper-atmosphere temperature measurements at remote sites and from research aircraft. Although OH airglow imagers are widely employed to study mesopause region dynamics, the OH lidar technique has been demonstrated only recently and few data have yet been collected using this new instrument.

System Design

Figure 1 is a block diagram of a typical resonance fluorescence lidar system. The pulsed laser is tuned to a resonant absorption line of the metallic species being probed. A small fraction of the output beam is directed to wavelength and energy monitors

and to a pulse detector, which triggers the data acquisition system. The laser pulse propagates into the atmosphere, where it is Rayleigh-scattered by air molecules at lower altitudes and then resonantly scattered by the metal atoms in the mesopause region. For resonance fluorescence scattering, individual metal atoms absorb photons in the laser beam and are excited to a higher energy state. Because the wavelength of the photons corresponds to an absorption line of the species, the probability of absorption is many orders of magnitude higher than the probability of Rayleigh scattering. In the low-density mesopause region, where the mean time between collisions is long compared to the fluorescence lifetime of the excited species, the excited atoms return to the ground state by spontaneously emitting a photon. In most cases, the emission wavelength is nearly the same as the excitation wavelength. Those photons that are backscattered into the receiving telescope and focused onto the photomultiplier tube are counted by the data acquisition system and then the data are recorded for later processing and analysis.

The detected photons are counted in small sequential subintervals of a few tenths of a microsecond duration, which correspond to scattering layers of a few tens of meters thickness. As in radar, the measured time delay between firing the laser and detecting the backscattered photons is used to compute the range to the scattering layer. To improve the signal level and minimize the effects of photon noise, the signal counts from several 100 laser pulses, transmitted over a period of several tens of seconds, can be integrated. This integration can be performed by the data acquisition system and/or in post-acquisition data processing to achieve a desired statistical significance in the measurement. The integrated data are then processed to yield profiles of the species concentration. If a narrowband laser is tuned to several different frequencies within the absorption line spectrum, it is also possible to infer the temperature and line-of-sight velocity of the species as well as its concentration.

Plotted in Figure 2 is an Na lidar signal profile obtained at the Starfire Optical Range near Albuquerque, NM. This lidar signal profile is a representative of resonance lidar signals from Na and other metals. The profile illustrates the molecular (Rayleigh) scattering between 30 and 60 km and the resonant scattering from Na between 80 and 105 km. The thin dense layers near 93 and 99 km altitude are meteor ablation trails that

Figure 1 Block diagram of a typical resonance fluorescence lidar system.

Figure 2 Na lidar photon count profile obtained at the Starfire Optical Range, NM on 17 November 1998 during the Leonid meteor shower.

drifted through the field-of-view of the lidar system during the 90 s observation period. The molecular scattered signal is proportional to atmospheric density, while the Na signal is proportional to the Na density.

Data Processing

For a zenith pointing lidar, the signal from a metallic scattering layer of thickness Δz located at an altitude z can be expressed in terms of the detected photon count as given by eqn [1].

$$N_m(\lambda, z) = \left(T_a^2 E^2(\lambda, z) \frac{P_L \Delta t}{hc/\lambda} \right) \times (\sigma_m(\lambda, T, v_R, \sigma_L) \rho_m(z) \Delta z) \times \left(\eta \frac{A_R}{4\pi z^2} \right) \quad [1]$$

In eqn [1], T_a^2 is the round-trip transmittance of the lower atmosphere; $E^2(\lambda, z)$ is the round-trip extinction associated with absorption by the metallic species; P_L is the average power of the laser; Δt is the accumulation period; h is Planck's constant; c is the vacuum speed of light; $\sigma_m(\lambda, T, \sigma_L)$ is

the effective absorption (or backscatter) cross-section of the resonance line, which is a function of laser wavelength λ , temperature T , radial velocity v_R , and laser linewidth σ_L ; $\rho_m(z)$ is the metallic species density; η is the overall optical efficiency of the receiving system including the detector; and A_R is the area of the receiving telescope. The first term in brackets on the right-hand side of eqn [1] is the effective number of transmitted photons; the second term is the probability that a transmitted photon is scattered by the metal layer of thickness Δz located at altitude z ; and the third term is the probability that a scattered photon is collected by the telescope and counted by the detector and data acquisition system. Because accuracy and useful resolution are related to signal strength, the most accurate, highest-resolution measurements are obtained with large power-aperture product ($P_L A_R$) lidars utilizing powerful lasers and large-diameter receiving telescopes. Typically, the laser average power levels are a few watts and the telescope diameters range from a few tens of centimeters to a few meters. Furthermore by taking the ratio of the resonance signal in the upper mesosphere and lower thermosphere (~ 70 – 110 km) to the Rayleigh signal in the stratosphere (~ 30 km), it is possible to remove the effects the

Table 1 Absorption cross-sections of several mesospheric metals

Metallic species	Nominal peak density (cm^{-3})	Resonance line wavelength (nm)	Peak absorption cross-section (10^{-16} m^2)
Ca	300	422.67	39
Ca ⁺	100	393.37	14
Fe	10 000	371.99	0.94
K	50	769.90	13
Li	3	670.78	7.3
Na	5000	589.00	15

atmospheric transmittance, optical efficiency, and laser power from the calculation of concentration, temperature, and wind.

A key strength of resonance lidar as a remote-sensing technique is that the scattering is described by the quantum mechanical interaction of light with atoms and molecules and unlike aerosol and cloud lidars is not dependent on particle shape, size, or orientation. The absorption cross-section can be calculated using the fundamental principles of quantum spectroscopy. The peak cross-sections for several mesospheric metals are listed in Table 1 along with the wavelength of the

Figure 3 Profiles of temperature, Na density, zonal wind, and meridional wind obtained with an Na wind–temperature lidar using the 3.5-m steerable telescope at the Starfire Optical Range, NM 2 November 2000.

absorption line. These cross-sections were computed by assuming that $T = 200$ K and $\nu_R = 0$, that the laser linewidth is small compared to the thermally broadened width of the absorption line, and that the laser is tuned to the peak of the absorption line. The nominal peak densities of these species usually occur between 90 and 95 km. The nominal densities are also listed in Table 1. The probability of resonance fluorescence scattering is given by the second term on the right-hand side of eqn [1]. The probability of scattering from a layer of Na 100 m thick with a nominal density of 5000 cm^{-3} is $7.5 \cdot 10^{-4}$. By comparison, the probability of Rayleigh scattering from air molecules in a 100-m-thick layer at 90 km is $3 \cdot 10^{-9}$. This simple example illustrates the enormous advantage of resonance fluorescence lidars for making observations in the upper mesosphere.

Measurement Capabilities

Na resonance fluorescence lidars were the first to be developed to measure wind and temperature profiles. These parameters are derived from the backscattered Na signal by tuning a narrowband laser over the Na D₂ fluorescence spectrum near 589 nm to measure the width of the fluorescence spectrum, which is related to temperature, and to measure the center frequency, which is related to Doppler shift associated with the radial winds. Na density, temperature, and radial wind velocity can be determined by measuring the backscattered signal at as few as three different frequencies within the D₂ spectrum. To measure all three wind components it is necessary to scan the lidar sequentially among several zenith and off-zenith directions using a steerable telescope. While simple in concept, Na wind-temperature lidars employ sensitive ring dye lasers, pulsed dye amplifiers, and complex frequency-locking techniques to achieve the required tens of kilohertz frequency accuracy necessary for the wind and temperature observations. Accuracies of ± 1 K and $\pm 1 \text{ m s}^{-1}$ (radial wind) at resolutions of ~ 100 m and ~ 1 min are readily achievable with current laser and telescope technologies. Plotted in Figure 3 are the temperature, Na density, zonal wind, and meridional wind profiles measured with a steerable Na lidar at the Starfire Optical Range, NM. Narrowband K and Fe lidars have also been used to measure temperature profiles using robust solid-state ring lasers. More recently, a rugged broadband Fe lidar was used to measure the first middle and upper-atmosphere temperature profiles over the North and South Poles using the Boltzmann technique.

Resonance lidar technologies are now making crucial contributions to the studies of the chemistry and dynamics of the middle atmosphere through measurements of constituents, winds, and temperatures. The high-resolution of resonance

lidar measurements not just allows measurements of these atmospheric state variables but also allow measurements of the constituent, heat, and momentum fluxes that are crucial for understanding nonlinear coupling and transport in the atmosphere. Resonance lidar systems are now part of instrument suites that make it possible to profile winds and temperatures throughout the atmosphere. These measurements are making fundamental contributions to our knowledge of this region and to the impact of global climate changes. During the 40 years since the invention of the laser, lidar technologies have firmly established themselves as one of the key tools for probing the Earth's atmosphere.

Introduction

Magnetospheres are new magnetic structures discovered during the space age by satellite-borne instruments that made possible physical measurements in distant regions previously not accessible. The first magnetosphere discovered was Earth's. Soon afterward, another discovery showed that space is not empty as once thought but is filled with ionized gases emanating from the Sun, stars, and other celestial bodies with high temperatures. It then became evident that magnetospheres are ubiquitous in space. What is a magnetosphere, how is it formed, and what are some of the important internal dynamics?

Let us first describe the environment in which magnetospheres are found. In our solar system, for example, the Sun's coronal atmosphere is hot, $\sim 10^6$ K, and dynamic, so it expands into space. The expanding solar coronal atmosphere is called solar wind and consists mostly of hydrogen ($\sim 95\%$ H^+) and helium ($\sim 5\%$ He^{2+}) ions and an equal number of electrons. Matter in the ionized state is called plasma and much of known matter in the Universe exists as plasmas. Since ionized matter is a good electrical conductor and magnetic fields decay slowly in conductors, it was immediately verified that the solar wind carries with it solar magnetic fields into space. Space is therefore permeated with magnetized plasma.

The solar wind is different from winds in the lower atmosphere because it is always blowing. All of the planets immersed in the solar coronal atmosphere are interacting with

it all the time. The electromagnetic (EM) interaction induces large-scale currents and forms magnetic cavities around magnetized planets. These cavities are called magnetospheres. Except for Mars and Venus, which do not have intrinsic magnetic fields, the planets in our solar system all have magnetospheres. This article will focus on planetary magnetospheres and emphasize features that are associated with Earth's magnetosphere, which has all of the elements to characterize a planetary magnetosphere (Figure 1).

The lower boundary of a planetary magnetosphere begins from that part of the atmosphere where ionized constituents play an important role in the dynamics of the upper atmosphere. For Earth, this boundary is located at ~ 100 km where the ionosphere begins (ionospheres are formed by the Sun's ultraviolet radiation). The ionosphere is therefore part of the magnetosphere. The outer boundary of the magnetosphere is called the magnetopause, and it separates the domains of the planetary magnetic field and the solar wind that blows outside it. Its location is determined by the pressure balance between the solar wind and the planetary magnetic field. On an average day Earth's magnetopause at local noon (subsolar point) crosses the equatorial plane at $\sim 10 R_E$ (average Earth radius, ~ 6367 km), and at $\sim 20 R_E$ in the dawn and dusk sectors. In the antisunward direction, the magnetosphere has a magnetic tail. The geomagnetic tail extends beyond $100 R_E$.

As the Sun's coronal atmosphere expands into space the wind speed increases, and near Earth's position it is ~ 400 $km s^{-1}$. This is faster than the speed of Alfvén waves in the

Figure 1 A sketch of Earth's magnetosphere in the noon–midnight plane. The dashed lines are the original dipole field. The solid lines are magnetic fields modified by external currents. IMF stands for interplanetary magnetic field, which is of solar origin. Major features of the magnetosphere are shown. (R_E earth radius.)

solar wind medium. Alfvén waves, named after the Swedish Nobel laureate Hannes Alfvén, are transverse magnetohydrodynamic waves travelling in the direction of the ambient magnetic field. As with objects that travel faster than the sound speed in the terrestrial atmosphere, a shock wave forms in front of Earth's magnetosphere. The Alfvén wave steepens nonlinearly and a shock forms as the magnetosphere plows through the super-Alfvénic solar wind. The Alfvén Mach number M_A is about 8, which makes the Earth's shock wave a strong shock. The shock wave is detached and separated from the magnetopause by $\sim 1 R_E$.

The region behind the shock wave is called *magnetosheath* and it extends to the *magnetopause*. The magnetosheath is a turbulent region permeated by large amplitude waves and hot particles that have been created in the shock formation. As in ordinary shocks, the solar wind stream energy is converted to the thermal energy. The solar wind speed in the downstream region just behind the shock is much reduced, $\sim 50 \text{ km s}^{-1}$. The solar wind speed picks up again further downstream.

Inside the magnetosphere, Van Allen radiation belts, named after their discoverer, James Van Allen, are found. These are divided into inner (ionosphere to $\sim 4\text{--}5 R_E$) and outer ($\sim 4\text{--}5 R_E$ to the magnetopause) radiation belts. The inner radiation belt energetic particles come from neutrons produced by cosmic rays that bombard the planet's atmosphere. Neutrons are unstable and have short lifetimes and they decay in flight into protons, electrons, and antineutrinos. The charged particles are captured by the planetary magnetic field. The primary source of Earth's energetic population in the inner radiation belt comes from these cosmic ray albedo neutron decay (CRAND) particles.

The source of the outer radiation belt particles is tied to solar wind and auroral disturbances which are dynamic. The outer magnetosphere is sometimes quiet, sometimes stormy, like the weather in the lower atmosphere of Earth. But unlike terrestrial weather, 'space weather' is driven by electrical forces powered by the disturbed solar wind connected to solar storms that produce flares and coronal mass ejections (CME). Spectacular auroral displays and intense radio emissions that occur in the polar regions of the planet are manifestations of space storms. The dancing lights of aurora are atmospheric emissions excited by precipitating energetic electrons that bombard the Earth's outer atmosphere. The radio emissions are generated by the unstable auroral particles.

Particles with millions of electron volt (MeV) energies are frequently produced during large space storms. These penetrating particles can impact on mankind as they can disrupt communication, impair satellite instrumentation and even cause damage to spacecraft. Another havoc is that currents of several million amps flow in the ionosphere during these storms. These ionospheric currents induce strong currents on the ground and have caused power outages in cities located in the auroral zone. A new practical goal of magnetospheric research is to learn to forecast space weather so as to forewarn when disruptive storms will occur and to predict which storms accelerate particles to MeV energies.

Particles in space rarely collide, because the density is so low and the mean free path so long. For example, in the outer magnetosphere there are ten thousand or so particles per cubic meter and in the solar wind a few million. The mean free path is

of the order of an astronomical unit, $1.5 \times 10^{11} \text{ m}$. This unique feature of the space system makes it different from other particle systems where collisions are prevalent.

Many space phenomena are driven by 'collisionless' processes that involve collective interactions through the long-range electromotive force. Very little is known about these collective processes. Even though it is known that the disturbed solar wind fuels auroral and magnetic storms, the actual mechanism of how the solar wind mass, momentum, and energy are transported across the magnetopause is not yet understood. The Earth's shock wave is a collisionless shock and, like ordinary shocks, it dissipates energy. But the collisionless dissipation mechanism is very different from the classical dissipation mechanism where viscosity is produced by the colliding particles. How viscosity is produced in a collisionless process is a fundamental problem yet to be solved.

Basic Equations

Understanding magnetospheres requires knowledge of how EM fields interact with charged particles and how large-scale currents are generated. The fundamental equations that describe the physics of magnetospheres are the Maxwell equations of electrodynamics,

$$\nabla \cdot \mathbf{B} = 0 \quad [1]$$

$$\nabla \times \mathbf{H} = \mathbf{J} + \frac{\partial \mathbf{D}}{\partial t} \quad [2]$$

$$\nabla \cdot \mathbf{D} = \rho \quad [3]$$

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \quad [4]$$

$\mathbf{B}$ is magnetic induction and is related to the magnetic field intensity $\mathbf{H}$ by the constitutive relationship $\mathbf{B} = \mu_0 \mathbf{H}$, where μ_0 is the magnetic permeability of free space and equal to $4\pi \times 10^{-7} \text{ Hm}^{-1}$, $\mathbf{D}$ is the electric displacement vector related to the electric field $\mathbf{E}$ by the constitutive relationship $\mathbf{D} = \epsilon_0 \mathbf{E}$ where ϵ_0 is the dielectric constant of free space equal to $8.85 \times 10^{-12} \text{ F m}^{-1}$, ρ is the charge density and $\mathbf{J}$ is the current density. The equations for ρ and $\mathbf{J}$ are given by

$$\rho = \sum_{\Delta V} \frac{q_k}{\Delta V} \quad [5]$$

$$\mathbf{J} = \sum_{\Delta V} \frac{q_k \mathbf{v}_k}{\Delta V} \quad [6]$$

where q_k and $\mathbf{v}_k$ are charge and velocity of the k th particle. The summation is carried over a suitably chosen small volume ΔV .

The velocity of the k th particle is obtained from the Lorentz equation of motion,

$$m_k \frac{d\mathbf{v}_k}{dt} = q(\mathbf{E} + \mathbf{v}_k \times \mathbf{B}) \quad [7]$$

There are as many equations of motions as there are particles and they are coupled through the electromagnetic fields. Equations [1], [2], [3], [4], [5], [6] and [7] plus the constitutive relationships define a system of charged particles and EM fields. The physics of magnetosphere studies the science of

large-scale electromagnetic dynamics with an extremely large number of particles, or alternatively it can be viewed as a branch of statistical physics of charged particles driven by electromagnetic forces.

Steady-State Magnetosphere

For an understanding of how magnetospheres are formed, and of the physics of the interaction that induces external currents strong enough to deform and modify the planetary dipole field and excite the dynamic activity inside the magnetosphere, eqns [1], [2], [3], [4], [5], [6] and [7] need to be solved self-consistently. But this is not yet possible. Even though the density in space is very small, a magnetosphere occupies a large volume and particles are interacting through the long-range electromagnetic field.

Our present knowledge of the magnetosphere is based primarily on the synthesis of various pieces of magnetospheric elements that have been studied. A quiet-time picture of the magnetosphere based on time-independent formulation is given below. This simple model is a reasonable starting point for describing the more real magnetospheres.

Magnetic Field

The equations that govern the time independent magnetic field are

$$\nabla \cdot \mathbf{B} = 0 \quad [8a]$$

$$\nabla \times \mathbf{H} = \mathbf{J} \quad [8b]$$

The solution of these equations is

$$\mathbf{B}(\mathbf{r}) = \frac{\mu_0}{4\pi} \int \frac{\mathbf{J}(\mathbf{r}') \times (\mathbf{r} - \mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|^3} d^3 r' \quad [9]$$

where use was made of $\mathbf{B} = \mu_0 \mathbf{H}$. Equation [9] is Biot-Savart's law and it states that given the current density $\mathbf{J}$ at $\mathbf{r}$, we can obtain the magnetic field $\mathbf{B}$ everywhere, or, given $\mathbf{B}$, we can invert the equation and obtain the source current $\mathbf{J}$ responsible for the magnetic field.

Equation [9] is difficult to use for the magnetosphere as a whole, because the particles contributing to the source term $\mathbf{J}$ are not completely understood and they have not been measured for all regions. Also, spacecraft-borne magnetometers have measured $\mathbf{B}$ over a large region of the magnetosphere but the magnetosphere is dynamic and single-point measurements made at different times are not easily related.

Information on $\mathbf{J}$ can be obtained if $\nabla \times \mathbf{B}$ can be measured. This requires simultaneous measurements with identical instruments from multiple spacecraft that can measure gradients of the magnetic field. This is one of the primary goals of the Cluster mission to be launched in the summer of 2000 by the European Space Agency (ESA). It is anticipated that Cluster experiments will definitely improve our knowledge of magnetospheric currents.

The Dipole Field

We begin with the dynamo current interior to the solid Earth, which is the source of the geomagnetic field. The dipole field is

a good approximation for describing the relatively stable magnetic field in the lower region of the magnetosphere. The dipole configuration also provides a standard of reference for many other planets and celestial bodies.

Let the dipole moment of the planet be given by $\mathbf{M}$. In regions outside the planet, there are no currents, hence $\mathbf{J} = 0$. We can then let $\mathbf{B} = -\nabla \Psi$, where Ψ is the magnetic scalar potential of a dipole given by

$$\Psi = \frac{\mu_0}{4\pi} \mathbf{M} \cdot \nabla \frac{1}{r} \quad [10]$$

Assume that Earth has a centered dipole moment $\mathbf{M}$ (Figure 2). In spherical coordinate system with $\mathbf{M} = -M\hat{z}$ (—for Earth), the three components of the dipole magnetic field are

$$\begin{aligned} B_r &= -\frac{\mu_0}{2} \frac{M}{\pi} \frac{\sin \lambda}{r^3} \\ B_\lambda &= -\frac{\mu_0}{4} \frac{M}{\pi} \frac{\cos \lambda}{r^3} \\ B_\phi &= 0 \end{aligned} \quad [11]$$

Figure 2 The top diagram shows the contours of the planetary dipole magnetic field. The magnetic moment for Earth points from north to south. The bottom diagram shows the Earth-centered coordinate system in which the dipole field is defined.

where for Earth $M = 8 \times 10^{22} \text{ A m}^2$, λ is the latitude ($\lambda = 0$ at the Equator) and r is the radial distance. $B_\phi = 0$ because the centered dipole is symmetric about ϕ . The magnitude of the field at (r, λ) is obtained from [11] and is given by

$$B(r, \lambda) = \frac{\mu_0}{4\pi} \frac{M}{r^3} (1 + 3 \sin^2 \lambda)^{1/2} \quad [12]$$

which shows r^{-3} dependence of the dipole field strength. A dipole has the strongest field at the pole ($\lambda = \pi/2$) and the smallest on the Equator ($\lambda = 0$). Another useful relation is the equation of the locus of a dipole field given by

$$r = r_0 \cos^2 \lambda \text{ and } \phi = \phi_0 \quad [13]$$

Here r_0 and ϕ_0 are distance and longitude of the line of force at $\lambda = 0$.

The dipole approximation is fairly good until about 4–5 R_E from the Earth. Further out, the magnetic field begins to depart as the other current sources become important.

Magnetopause

Consider now the dayside boundary of the magnetosphere. For simplicity, consider the boundary to be a plane and assume the solar wind consists of electrons and protons. The planetary magnetic field is in vacuum (no particles in the magnetosphere) and the solar wind is not magnetized (no interplanetary magnetic field). The solar wind particles that impinge on this boundary are deflected by the Lorentz force. This creates a boundary current running from east to west and modifies the planetary field.

In Figure 3, the total magnetic field B_t produced by the current just inside the boundary can be estimated as

$$B_t = B_d + B_s \quad [14]$$

where B_d is the dipole field of the planet at that point and B_s is the surface magnetic field produced by the magnetopause current. Just outside the boundary,

$$B_t = B_d - B_s = 0 \quad [15]$$

Therefore,

$$B_t = 2B_d \quad [16]$$

This result states that the current at the magnetopause will produce a magnetic field whose intensity is twice the value of the undistorted dipole field at that point. It is based on an ideal model which stipulates the planetary field to totally vanish inside the solar wind.

The magnetopause boundary separates the two domains completely and there is no normal component of the magnetic field in this model. This magnetosphere is essentially the model proposed by S. Chapman and V. C. A. Ferraro in 1931 to explain terrestrial magnetic storms. This magnetosphere is 'closed' and particles cannot enter the magnetosphere. If the boundary supports a normal component of the magnetic field, it can lead to an 'open' magnetosphere which allows the particles to enter the magnetosphere from the solar wind (see 'Dynamic Magnetosphere' below).

If the boundary is curved then the same procedure can be used, but now currents that give curved field configurations need to be taken into account. Another feature not incorporated

Figure 3 The top sketch shows a boundary in the noon–midnight plane that separates the solar wind and the magnetosphere. The current at the boundary is out of the page. The bottom sketch shows how the current is set up by the turning around of the solar wind particles due to the Lorentz force.

in this simple pedagogic model is that the real magnetopause includes a boundary layer. How boundary layers can be produced in collisionless plasmas is still not understood.

We can estimate where the outer boundary is located. Let the solar wind be specularly reflected at the boundary. The transfer of momentum per particle per collision is $2mV_{sw} \cos \xi$, where m is the mass of H^+ , V_{sw} the velocity of the solar wind, and ξ the angle of incidence. The number of particles striking a unit area of the boundary per second is $NV_{sw} \cos \xi$, where N is the number density of the solar wind. Thus, the total energy density of the particles perpendicular to the surface is $2NmV_{sw}^2 \cos^2 \xi$. At the magnetopause boundary, we require a balance between the solar wind and planetary magnetic energy densities. Hence,

$$2NmV_{sw}^2 \cos^2 \xi = B^2/2\mu_0 \quad [17]$$

Typical values are $V_{sw} = 400 \text{ km s}^{-1}$ and $N = 5 \times 10^6 \text{ m}^{-3}$. Equation [17] then yields $B \approx 70 \text{ nT}$ for the subsolar point, $\xi = 0$. From equation [16], we see that in the absence of the solar wind, the undistorted dipole field has a value approximately $\sim 35 \text{ nT}$. The surface field of Earth is $\sim 0.32 \times 10^{-4} \text{ T}$. Scaling this as $1/r^3$, we deduce the location for the magnetopause to be $\sim 9.2 R_E$. Observations show the subsolar magnetopause position varies typically between $\sim 9 R_E$ and $11 R_E$.

Geomagnetic Tail

The solar wind imparts momentum on the planetary magnetic field and creates a current such that when superposed on the dipole field, the resulting field on the antisunward direction has a tail-like geometry (Figure 1). The equation $\nabla \times \mathbf{H} = \mathbf{J}$ shows that a line or sheet current in the x -direction with the current flowing from dawn to dusk in the noon–midnight plane is needed. Several functional models have been proposed to account for the tail geometry. One model of this current is given by

$$J_y = \frac{B_0}{\mu_0 L} \sec h^2 \frac{z}{L} \quad [18]$$

where B_0 is the magnitude of the magnetic field at the outer boundary and L the half-thickness in the z -direction. This current is uniform in the y -direction but has a z -dependence. The magnetic field deduced from eqn [18] yields

$$B_x = B_0 \tanh \frac{z}{L} \quad [19]$$

The magnetic field is directed along the x -direction and increases with z . The magnetic field vanishes at $z = 0$. This is the magnetic field free line (neutral line) that results from the fields above and below that point in opposite directions. While functional models provide a useful picture of how the tail might be formed, the structure of the real tail current is very complicated. Although it is attributed to the solar-wind–geomagnetic-field interaction, how the current is produced and maintained is still unknown.

Electric Field

Understanding the origin of electric fields in magnetospheres is important because they can change particle energies and also alter their trajectories. For example, in the presence of an electric field perpendicular to the direction of the magnetic field, the particles drift across the magnetic field (further discussion below).

The two Maxwell equations governing the electric field for static magnetospheres are

$$\nabla \cdot \mathbf{D} = \rho \quad [20a]$$

$$\nabla \times \mathbf{E} = 0 \quad [20b]$$

The electric field can be defined in terms of the scalar potential ϕ , $\mathbf{E} = -\nabla\phi$, which inserted in eqns [20a] and [20b] yields Poisson's equation,

$$\nabla^2 \phi = \rho \quad [21]$$

whose solution is

$$\phi(\mathbf{r}) = \frac{1}{4\pi\epsilon_0} \int \frac{\rho(\mathbf{r}') d^3\mathbf{r}'}{|\mathbf{r} - \mathbf{r}'|} \quad [22]$$

where $\mathbf{r}'$ is the location of the charge density and the potential is evaluated at $\mathbf{r}$. This is the Coulomb potential that results from the charge density ρ . Electric field is obtained by taking the gradient of ϕ . Although magnetospheres are populated by charged particles, free charges ρ are not maintained (charges do not accumulate in good conductors). Thus, eqn [22] is not useful when considering large-scale electric fields in space.

Large-scale electric fields in magnetospheres are produced mainly by inductive effects. Michael Faraday in 1831 showed that an electromotive force (e.m.f.) is induced when magnetic flux changes in time or in space. In the magnetosphere, the inductive field comes from motions of a plasma across a magnetic field or rotation of a magnetized planet through a plasma medium. These motions induce a motional e.m.f., which is the primary source of large-scale electric fields in space.

Motional Electric Fields

Electric and magnetic fields are measured on moving platforms through a plasma medium which itself may be in motion. The relationship of electric and magnetic fields in the rest and moving frames of references is given by the Lorentz transformation. For linear motions and nonrelativistic case ($V/c \ll 1$), the relations are

$$\mathbf{E}' \approx \mathbf{E} + \mathbf{V} \times \mathbf{B} \quad [23a]$$

$$\mathbf{B}' \approx \mathbf{B} \quad [23b]$$

Here the prime (') denotes a moving frame and $\mathbf{V}$ is the velocity of that frame relative to the rest frame (unprimed) and c is the speed of light. Magnetic fields measured in the two frames are nearly equal, but electric fields are different. Thus, it is necessary to specify the coordinate frame in which the measurements are made.

An important result of the Lorentz transformation is that if the velocity of the moving frame is given by

$$\mathbf{V} = \frac{\mathbf{E} \times \mathbf{B}}{B^2} \quad [24]$$

then $\mathbf{E}' = 0$ and no work will be done on the particles in that moving frame. This has important application for plasma systems in motion. Consider, for example, the motion of an arbitrarily shaped system of charged particles in the magnetosphere. Lorentz's result states that if the motion of this plasma is given by eqn [24], then $\mathbf{E}' = 0$. Thus, the electric field vanishes in the moving frame which is also the plasma frame of reference. Equation [23a] then states

$$\mathbf{E} = -\mathbf{V} \times \mathbf{B} \quad [25]$$

The electric field in the rest frame is related to the vector product of the velocity of the plasma system and the magnetic field.

Equations [24] and [25] are equivalent expressions. These equations state that if there is an electric field, the plasma will move. Equivalently, if the plasma is moving, there is an electric field. In a manner analogous to the convective motion in fluids which arises to equalize the nonuniform temperature, the plasma motion arises to transform away the electric field (charges) in the moving frame (plasma frame) because free charges cannot be maintained in good conductors. In that sense, the plasma motion in eqn [24] is referred to as a convective motion.

If the coordinate frame is spinning, this frame is not an inertial frame and the Lorentz transformation theory is not valid. General relativity effects must be taken into account. We state only the results here. The relationships of EM fields are given by

$$\mathbf{E}'' = \mathbf{E} + \mathbf{V} \times \mathbf{B} \quad [26a]$$

$$\mathbf{B}'' = \mathbf{B} \quad [26b]$$

where the double prime (") denotes the spinning frame of reference, $\mathbf{V} = \boldsymbol{\omega} \times \mathbf{r}$ and $\boldsymbol{\omega}$ is the angular frequency vector. Equations [23a], [23b], [26a] and [26b] have the same form, except that eqns [26a] and [26b] are exact to all orders in V/c , whereas eqns [23a] and [23b] are only approximate.

Electric Field at the Magnetopause

In closed magnetospheres, Maxwell equations require the tangential component of the electric field to vanish at the boundary, in addition to the requirement of the absence of a magnetic normal component. The presence of a tangential electric field will allow particles to drift across the boundary which is not permitted in closed models. This contrasts the open model which invokes a magnetic field merging process (see 'Dynamic Magnetosphere' below). In closed models, particles can cross the boundary, for example, by diffusive mechanisms.

Electric Field in the Plasma Sheet

The geomagnetic tail is populated by plasmas of the solar wind and the ionosphere. When these plasmas move, we can apply the above results to study the behavior of the electric field. Although the motions are generally turbulent, we will assume the motion is laminar. Consider an observer on the equatorial plane at rest observing the plasma moving toward the Earth. Equations [23a] and [23b] can be used to estimate the magnitude and direction of the electric field. For example, in the noon-midnight meridional plane, $\mathbf{V}$ is earthward and $\mathbf{B}$ is upward, and thus the electric field $\mathbf{E}$ points from dawn to dusk. The dawn-dusk electric field measured during quiet solar wind and geomagnetic field is $\sim 0.3 \times 10^{-3} \text{ V m}^{-1}$. The origin of this large-scale dawn-dusk field is thought to be the solar wind, but the mechanism for establishing this field across the tail of the magnetosphere is not known.

Electric Field in the Plasmasphere

The Earth's rotation is important for particles in the lower region of the magnetosphere. This region, dominated by the dipole field and populated mostly by ionospheric plasmas, is called plasmasphere. The plasmasphere starts from the ionosphere and extends out to about 4–5 R_E in the equatorial plane. It thus includes the inner radiation belt. The boundary of the plasmasphere is called plasmopause. Outside this boundary is the outer radiation belt.

The rotation of the planet induces an electric field in the plasmasphere. Consider an observer at rest at position $\mathbf{r}$ on the equatorial plane. Noting the plasma is rotating with the planetary angular frequency they apply eqns [26a] and [26b] to calculate the induced electric field. Since the electric field in the rotating frame (plasma frame) vanishes, they use

$$\mathbf{E} = -(\boldsymbol{\omega} \times \mathbf{r}) \times \mathbf{B} \quad [27]$$

to find the direction and magnitude of $\mathbf{E}$. The result shows the electric field is radially outward. Induced electric field due to

the rotation of the planet is also known as the corotational electric field. The Earth's corotational electric field is $\sim 0.5 \times 10^{-3} \text{ V m}^{-1}$ at ionospheric heights.

Van Allen Radiation Belts

The motion of a charged particle is governed by the Lorentz equation of motion given in eqn [7]. We can study the behavior of a single particle using this equation, neglecting the presence of other particles. This test particle approach will give us a sense of how a charged particle moves around in magnetospheres and how Van Allen radiation belts are formed. Since we are ignoring the collective effects of interacting particles, information on the dynamic behavior of magnetospheric particles in aurorae is not revealed.

Consider first the motion of a particle in a time-independent magnetic field and assume there is no electric field ($\mathbf{E} = 0$). The equation of motion is then $m d\mathbf{v}/dt = q\mathbf{v} \times \mathbf{B}$. In inhomogeneous magnetic fields, $\mathbf{B} = \mathbf{B}(\mathbf{r})$, this differential equation yields three types of motion. The first is the cyclotron motion around the magnetic field. The cyclotron frequency of this circular motion is $\omega_c = qB/m$ and the cyclotron radius is $r_c = mv_{\perp}/qB$. Here $v_{\perp}$ is the magnitude of the particle velocity perpendicular ($\perp$) to the magnetic field direction. In terms of the pitch α of the particle, the angle between the particle velocity $\mathbf{v}$ and the magnetic field $\mathbf{B}$, $v_{\perp} = v \sin \alpha$.

The second type of motion comes from particles with $\alpha \neq \pi/2$. These particles can move along the direction of the magnetic with $v_{\parallel} = v \cos \alpha$. Here $\parallel$ denotes parallel to $\mathbf{B}$. In an inhomogeneous magnetic field such as the dipole field, the field becomes stronger as the particle gets closer to the planet. The particle orbit winds tighter as it approaches the stronger field region and it also encounters a force that pushes the particle back in the direction from which it arrives. This results in 'mirroring' of the particles, which bounce back and forth between the Northern and Southern Hemispheres.

The third type of motion comes from particles travelling on magnetic fields that are curved and not uniform in the radial direction. Particles travelling on curved magnetic fields experience a centrifugal force. Particles in fields that are not uniform experience a continually changing cyclotron radius. Both of these effects result in particle drifts in the azimuthal direction, westward for positively charged particles and eastward for negatively charged particles. The curvature and gradient drift velocities are energy-dependent, with higher energy particles drifting faster.

In the presence of electric fields, the motions described above must now be augmented with the effects of electric fields. Consider a time-independent electric field given by $\mathbf{E} = \mathbf{E}_{\parallel} + \mathbf{E}_{\perp}$, where the $\parallel$ and $\perp$ are directions relative to the direction of the magnetic field. The effect of $\mathbf{E}_{\parallel}$ is to accelerate or decelerate particles travelling along the magnetic field. $\mathbf{E}_{\perp}$ gives rise to a drift in the azimuthal direction given by eqn [24]. A peculiar feature here is that the drift is the same for $+$ and $-$ particles and also independent of the mass, charge, and energy of the particles.

In summary, the total motion of particles in magnetospheres consists of a superposition of the cyclotron motion, bounce motion and the drift motion. In the absence of $\mathbf{E}_{\parallel}$ these

are energy-conserving motions. In the outer radiation belt at synchronous altitudes ($\sim 6.6R_E$ geocentric) for example, the electron cyclotron frequency is ~ 1 kHz, the bounce period for 40 keV electrons is ~ 1 s, and the drift period is ~ 2 hours. For the ions, the cyclotron frequency is smaller by the ratio of electron to ion mass, the bounce frequency by the square root of the mass ratio, and the drift times are same for the same energies.

The lifetime of the magnetospheric particles is determined by how close they approach the planetary atmosphere. If they approach close to the planet where the atmospheric densities are sufficiently high, so that they collide with them, then these particles will be lost into the atmosphere. These are called precipitated particles and they are the source of atmospheric emissions responsible for aurorae at high magnetic latitudes. If the particles bounce at sufficiently high altitudes where collisions are infrequent then these particles can persist for a long time and drift around the magnetosphere many times. These particles are trapped particles and they form the Van Allen radiation belts.

Dynamic Magnetosphere

Contrary to the static magnetosphere described above, the real magnetosphere is time-dependent and very dynamic. As an example, we describe phenomenologically what happens when the solar wind is moderately disturbed. The magnetopause boundary moves in and out in response to the solar wind variations. The boundary is no longer smooth but is modulated with surface waves, reminiscent of atmospheric and ocean waves in stormy weather. These magnetopause waves could be excited by the Kelvin–Helmholtz instability mechanism owing to the presence of the large solar wind velocity shear across the boundary. Inside the magnetosphere, particles are injected from the plasma sheet into the outer radiation belt, and trapped Van Allen particle intensity and energy increase by orders of magnitude. This happens when the tail current abruptly disrupts and the geomagnetic field returns for a short time to the dipole shape. The trapped particle intensity increases considerably during magnetic storms and the particles form a ‘ring current’ at $\sim 4R_E$ strong enough to affect the terrestrial magnetic field measured on the ground. In the polar ionosphere, brilliant and wild auroral displays luminate the night sky accompanied by the roaring of natural electromagnetic radio waves that are emitted over millihertz to megahertz frequencies. The geomagnetic tail wags and flaps like a wind sock on a windy day. An observer in the interplanetary space sees the magnetosphere soaring through the heliosphere with bright flickering lights, resembling a comet.

Unable to solve eqns [1], [2], [3], [4], [5], [6] and [7] in a self-consistent way, space researchers have thus far obtained only approximate solutions. For this reason, the picture of the magnetosphere is incomplete. The approach most commonly used has been to treat the collisionless space plasmas as a magnetohydrodynamic (MHD) fluid and then solve the

mass, momentum, and energy conservation equations using the variables of density, velocity, and temperature. MHD theory has provided insight into the ways the solar wind flows and how magnetospheres respond to the solar wind. An important paradigm of the MHD theory is that interplanetary and Earth’s dipole magnetic fields can ‘merge’, which opens the magnetosphere so the solar wind can enter. This innovative concept was introduced by James W. Dungey nearly 40 years ago. The physics of merging requires a kinetic treatment which has not yet been solved.

A limited number of dynamical processes have been studied from the kinetic point of view, assuming that an ensemble of collisionless particles can be defined in terms of the distribution function. One then solves the Boltzmann transport equation coupled to the EM equations. This approach has been most fruitful in the study of the microphysics of wave–particle interactions and instabilities. Progress has been made towards understanding the microphysics of auroras observed at ionospheric heights, and much has been learned about the structure of aurorae, how particles are accelerated in the ionosphere and how certain types of radio emissions are excited. The full kinetic formulation has not however been applied to problems of large-scale global spatial structure and dynamics, and this will remain at the forefront of magnetospheric studies.

Among the important dynamic problems to be studied in magnetospheres include how the solar wind gets into the magnetosphere, how the particles are accelerated in the magnetosphere, how electric fields are set up in the geomagnetic tail, how the magnetosphere and the auroral ionosphere are coupled, how global currents can be generated during auroral storms to reconfigure the entire magnetosphere and how some of the solar wind energy is captured to produce the global aurora.

Synopsis

Mesoscale meteorology occurs in the range of horizontal scales between larger, synoptic-scale and smaller boundary-layer scales. The mesoscale includes many of the weather systems with the highest societal impact, including cumulonimbus storms, intense cyclones and locally generated winds. Weather systems on the mesoscale also control many transport processes in the global atmosphere, causing rapid movement of air from the boundary layer to the upper troposphere. This article reviews the physical processes which control weather systems on the mesoscale, and their mathematical representation, then makes a broad survey of some important mesoscale phenomena.

Introduction

The mesoscale is an intermediate regime between the larger, synoptic scale and the smaller scales of boundary layers, turbulence and micrometeorology. The fact that the mesoscale is an intermediate regime is reflected in the physical processes, which influence mesoscale systems. While larger, synoptic-scale systems can be regarded as being close to geostrophic balance, and small-scale systems are variously independent of Coriolis force, compressibility or nonhydrostatic effects, at the mesoscale we cannot immediately neglect any components of the equations of motion, except for effects associated with the Earth's curvature. In a sense, the mesoscale could be defined as the regime in which all the physical processes represented in the basic dynamic and thermodynamic equations of the atmosphere may be important. By necessity, this article refers in only superficial detail to a wide range of phenomena and processes, each of which is discussed in more detail in separate articles.

Since it spans a range of phenomena and processes, the mesoscale is often subdivided into the rather unmemorable categories of,

- meso- α : 200–2000 km, e.g., secondary frontal cyclones,
- meso- β : 20–200 km, e.g., mesoscale convective systems (MCSs), and
- meso- γ : 2–20 km, e.g., cumulonimbus cells.

Since these categories are in order of roughly increasing Rossby number (defined as $Ro = U/fL$, with U and L the velocity- and lengthscales and f the Coriolis parameter), they correspond to a decreasing importance of planetary rotation and geostrophically balanced dynamics.

The relegation of mesoscale meteorology to a transition zone between larger and smaller scales of the atmosphere is to belie the fact that the mesoscale exhibits a majority of the most interesting, observable weather systems. Many of these systems are of the highest societal impact. These include cumulonimbus storm cells and cumulonimbus complexes, a variety of

frontal structures, and various coherent flows relating to topography or coastal regions. These systems are fascinating as remarkably coherent and repeatable structures in a nonlinear and complex dynamical regime of the atmosphere. Mesoscale systems are also important practically, being responsible for producing damaging storms (such as squall lines, supercells, mesoscale convective complexes, secondary frontal cyclones, polar lows, and downslope windstorms), complex rainfall distributions, and significant inhomogeneity in local weather conditions. In addition, cumulonimbus convection and active fronts are the two families of systems responsible for rapid vertical transport of trace gases from the boundary layer (where most natural and anthropogenic sources exist) to the upper troposphere and lower stratosphere. Such weather systems are poorly resolved or parametrized in global-scale models, and they are critical to global-scale chemical transport.

Increasing computer power over recent decades has led to a rapid increase in the possibilities for numerical modeling of mesoscale phenomena. In the study of cumulonimbus convection, for example, simulations of evolving cloud systems have been able to explore the sensitivity of such storm systems to environmental parameters (such as background winds and thermodynamics), with useful benefit to forecasting. As remarked above, these kinds of simulations tend to contain all the components of the dynamic and thermodynamic equations, since they relate to a scale where nothing can be wholly neglected, and are often termed ‘full physics’ simulations. Indeed, simulations of MCSs are performed using ‘large eddy’ simulations incorporating explicit cloud microphysics as well as the influence of the Coriolis acceleration.

Until recently, the resolution of global-scale models has meant that representation of mesoscale systems has by necessity involved subgrid parametrization. Currently, however, the horizontal resolution of global operational models is approaching the mesoscale, and we are left with a delicate balance between what is resolved and what is parametrized: if a model has resolution of 25 km, and the coherent convective structures are of a similar scale, the convective structures are neither well-resolved nor well-parametrized.

Despite the increasing possibilities of mesoscale numerical modeling, the observed coherence of mesoscale weather systems, in the sense that the same coherent structures are observed on many occasions, points to the importance of idealized and intuitive interpretations of the atmospheric dynamics, and this remains an active area of research. The simple model of the density current, for example, is very efficient at obtaining robust estimates of the propagation characteristics of small-scale fronts, is intuitively easy to understand, and requires some considerable effort to better with a numerical model.

Mathematical Description of Different Mesoscale Regimes

The only universal simplification appropriate to all mesoscale systems is to neglect effects of the Earth’s curvature and consider an f -plane version of the ‘primitive equations’ (which represent a shallow layer on the quasi-spherical Earth).

The resulting equations of motion can be cast in different forms, depending on the choice of vertical coordinate: here they will be stated in physical height coordinates. The vector momentum equation is,

$$\frac{D\mathbf{u}}{Dt} + f\mathbf{k} \times \mathbf{u} = -g\mathbf{k} - \frac{1}{\rho}\nabla p' + \frac{\partial \tau_{ij}}{\partial x_j}, \quad [1]$$

where $\mathbf{u}$ is the vector velocity, $\mathbf{k}$ is the upward unit vector, g is the acceleration due to gravity, ρ is the density, p' the perturbation pressure, and τ_{ij} is the Reynolds stress tensor, with the summation convention assumed for this last term. The system also requires a thermodynamic equation,

$$\frac{D\theta}{Dt} = S, \quad [2]$$

where θ is the potential temperature and S is a thermodynamic source term (say due to radiative flux convergence or phase changes of water and including a term according to the divergence of the turbulent flux of potential temperature) and conservation of mass, or continuity,

$$\frac{D\rho}{Dt} + \rho\nabla \cdot \mathbf{u} = 0. \quad [3]$$

Turbulence Closure

The momentum and thermodynamic equations involve turbulent fluxes on the right-hand side, which need to be obtained by some form of turbulence closure. Although a great deal of effort can be expended on dealing with the turbulent terms, there are no schemes which are entirely satisfactory. The most reliable approach for numerical modeling is regarded to be large eddy simulation, in which, crudely speaking, a spatial resolution is chosen to resolve the anisotropic scales of eddies, with the assumption that smaller (isotropic) scales can be dealt with effectively by a relatively simple turbulent scheme. In practice, the resolutions required by this method, on the order of meters, mean that computational demands are extremely high when mesoscale systems on the scales of 10 km or more are studied.

For some flows, such as small-amplitude buoyancy waves, the turbulence terms will be very small, but most mesoscale systems involve turbulent mixing to an important degree.

Simplifications to the Continuity Equation

In most instances the continuity equation may be simplified using the assumption of subsonic flow, to the anelastic form,

$$\nabla \cdot (\rho_r \mathbf{u}) = 0, \quad [4]$$

in which $\rho_r(z)$ is a reference density which depends only on height, z . If, as in the case of a sea breeze current, the vertical scale of the motion is small relative to the scale height,

$$H = \frac{R\bar{T}}{g} \sim 8 \text{ km}, \quad [5]$$

where R is the gas constant for air and $\bar{T}$ is a mean temperature for the atmosphere, it is possible to use the incompressible form,

$$\nabla \cdot \mathbf{u} = 0. \quad [6]$$

There are few instances where one of these approximations will not be valid, but it should be recalled that deep waves in the atmosphere have speeds, which scale approximately with the vertical wavelength. In a quiescent atmosphere of constant static stability, the maximum group and phase speeds of buoyancy waves are

$$c = \frac{N}{m}, \quad [7]$$

where N is the Brunt–Väisälä frequency and m is the vertical wave number: for a wave with a single maximum in the troposphere this can be of the order of 50 m s^{-1} , while for a wave with a first maximum at the tropopause it can be 100 m s^{-1} . Further refinements to the continuity equation exist, and have been proposed to take into account such very deep motions.

Hydrostatic Balance

It is often possible to assume a state of hydrostatic balance, provided the vertical scale of the motion is significantly smaller than the horizontal scale, which tends to imply the meso- α regime. This is, for example, applicable to most scales of frontal dynamics, but not to the circulations in a cumulonimbus storm. For inertia-gravity waves, the applicability of hydrostatic balance depends on the aspect ratio of the waves, being suitable when the ratio of horizontal to vertical wave numbers, k/m , is small.

The Boussinesq Approximation

This approximation amounts to neglecting density variations in inertia terms but retaining them from the point of view of buoyancy, which is valid when the vertical scale of the motion is much less than the scale height, H . A basic state density field $\rho_r(z)$, dependent only on height, is then incorporated into a modified pressure function. This is very convenient in that it retains the simplicity of uniform, incompressible dynamics, while accommodating buoyancy variations. There are several versions of the Boussinesq approximation: typically it leads to momentum equations of the form,

$$\frac{D\mathbf{u}}{Dt} + f\mathbf{k} \times \mathbf{u} = g'\mathbf{k} - \nabla\phi + \frac{\partial\tau_{ij}}{\partial x_j}, \quad [8]$$

where $\phi = p'/\rho_r$ is the modified pressure and g' is the buoyancy.

Semigeostrophic Theory

The semigeostrophic (SG) model is a refinement of quasi-geostrophic (QG) dynamics, to allow for short lengthscales in the region of a synoptic front. This approach, although based on balanced dynamics, is thought to work effectively in quasi-two dimensional frontal zones down to scales of tens of kilometers, and is therefore one of the few areas where analytical, mathematical theory has been able to bridge the mesoscale regime. Broadly, SG frontal dynamics involves an along-front component of the wind, v_g , in geostrophic balance with the cross-frontal pressure structure, but also accommodates advection by the ageostrophic cross-frontal and vertical winds (a feature which is absent from QG dynamics). This is made

analytically more tractable by transformation to a geostrophic momentum coordinate,

$$X = x + \frac{v_g}{f}, \quad [9]$$

where x is the cross-front direction. The transformation between coordinate systems can develop a singularity in finite time, and mathematically it is this which leads to the formation of frontal singularities in the model; physically, it is the process of advection by the ageostrophic winds, which leads to the enhanced frontogenesis.

SG models are based on thermal wind balance, which states that the vertical gradient of the geostrophic wind is proportional to the horizontal gradient of the temperature. Using this balance SG models can conveniently be solved by inversion of a conserved (in the absence of diabatic processes) potential vorticity function. This makes SG potential vorticity a powerful quantity with the properties that it is conserved moving with the flow, and that the temperature and wind patterns can be retrieved from it. Weather patterns can be identified in terms of their coherent potential vorticity patterns, which then move with the weather system, and define the winds and temperatures in this system. This has major advantages relative to (for example) studying weather systems in terms of their surface pressure patterns, since the surface pressure is not conserved, changing as the weather system moves.

The inversion procedure for SG potential vorticity fails when the potential vorticity becomes negative, a condition, which implies 'slantwise instability' of the atmosphere.

Higher order balance models have also been applied to mesoscale phenomena such as organized convective systems. However, the prevalence of latent heating and turbulent processes, as well as the difficulty of applying a balance condition at high Rossby number, has meant that the use of potential vorticity concepts is less common to mesoscale systems than it is in synoptic analysis.

A Tour of Mesoscale Phenomena

Buoyancy Waves

Often termed 'gravity waves' these patterns occur as a universal response of the stably stratified atmosphere to mesoscale perturbations. They propagate with components in the vertical and horizontal, and are modified strongly by the vertical structure of both stratification and horizontal wind. For shallow waves, for which k/m becomes small, the waves are increasingly influenced by the Coriolis terms, and are known as inertia-gravity waves. Two characteristic regimes of solution are upward-propagating waves, which carry energy and momentum upwards away from the wave source, and trapped waves, where a wavelike region is bounded by an evanescent layer, leading to ducting of the waves in the horizontal. Although simple, linear buoyancy wave solutions for a quiescent, Boussinesq atmosphere are relatively easy to obtain, for real profiles it seems that detailed consideration of the full vertical profile is necessary in order to diagnose the correct buoyancy wave characteristics.

In regions of orography, vertically propagating waves tilt backwards against the mean flow (Figure 1(a)), and the

Figure 1 Schematics of streamlines over a hill in the cases of (a) upward wave propagation and (b) wave trapping. In (a) the wave tilt with height contributes to a wind speed maximum in the lee.

resulting shift in the streamlines contributes to downslope acceleration of the wind. In conditions of trapping (**Figure 1(b)**), lee waves can propagate significant distances downstream and can often be seen in low-level cloud patterns (**Figure 2**). Such lee waves give rise to local regions of low-level convergence, which may occasionally initiate moist convection.

Deep convection forces waves propagating both upward into the stratosphere and horizontally in the troposphere: deep modes in the troposphere propagate at speeds upward of 50 m s^{-1} , and evidence of wave-trains forced by convection has been observed in the small surface pressure changes measured by arrays of microbarographs.

The horizontally propagating waves act to modify the environment of the convection, through adiabatic warming and cooling, and are one mechanism whereby the convection communicates its thermodynamic forcing into its environment. The primary mode of response to the convective heat

source is downward motion, warming the environment: heating and strong ascent within a convective cloud causes subsidence in its environment, and this region of subsidence spreads outwards with gravity wave propagation. Within the subsidence region the air warms through adiabatic descent, meaning that the heating within the cloud (due to cloud condensation) has caused heating of the environment through subsidence. Although the heating profile of a cumulonimbus storm is dominated by midlevel warming, the vertical structure of the heating (including forcing due to downdraft cooling) forces modes of different vertical structure. As in the case of orographic waves, there is an important possibility of wave ducting, if waves are trapped in the troposphere, in which case a strong response can occur at large distances.

Generation of buoyancy waves by orography and by convection and the subsequent momentum flux convergence when the waves break are thought to be significant processes in the global circulation. However, neither wave source, whether orographic or convective, is ideally represented in global models. Diagnosis of the relevant wave regime is not easy, and waves may propagate long vertical or horizontal distances, equivalent to many model gridlengths, before breaking.

Cumulonimbus Convection

Cumulonimbus storms are the most dramatic of cloud features, and are a vital component in the atmospheric circulation. Individual cumulonimbus cells occur on horizontal scales of around 10 km and commonly extend to the tropopause, over a timescale of an hour or so (**Figure 3**). However, it is common for cumulonimbus systems to self-organize into an MCS with a significantly longer life cycle: squall lines in West Africa can persist for 48 h and propagate for thousands of kilometers across the continent.

Cumulonimbus storms involve rapid and active microphysical transitions, among water vapor, cloud drops, rain, and many forms of ice. The microphysical changes occur on time-scales of a few minutes, yet the storm systems can persist for many hours and organize into a significant degree of geostrophic balance, so these systems can truly encompass the

Figure 2 Linear bands of cumulus, representing low-level 'gravity wave clouds,' observed at West Lutton in Yorkshire at 1937 UTC on 1 June 2011. On this day, similar clouds were observed over large parts of the UK.

Figure 3 A typical cumulonimbus storm, observed near Varberg, Sweden, 1336 UTC on 6 August 2005.

whole mesoscale atmospheric regime. In terms of mathematical representation, the strong up- and downdrafts in these storms, combined with intense turbulence and their great depth, mean that none of the mathematical approximations outlined above can comfortably be applied (although the anelastic approximation may be used if the fast buoyancy wave response is not critical to the solution). Cumulonimbus systems also involve other distinct mesoscale flows as components, or responses to the forcing. The buoyancy wave response has been discussed above; other component flows include the cold pool and its gust front. Within a cumulonimbus storm, evaporation in the precipitation-driven downdraft causes the cold pool of air at the surface, and this propagates like a density current, of around 1 km depth, into the environmental boundary layer. Forced lifting at the gust front acts to trigger new convective cells (Figure 4). Although the gust front spreads in all directions outward from its source, the lifting is optimized in a given direction in relation to the ambient wind, and this in turn feeds back on the morphology of the cumulonimbus system. For instance, when regeneration of new convective cells occurs on one side of a storm, due to favorable interaction with the ambient winds on that side, this leads to development of the convective system in that direction. In some cases, where there is a balance between the ambient flow and the cold pool, stationary storms can develop, and these can lead to long periods of intense rainfall on a fixed location, with the possibility of flash flooding.

The interaction between boundary-layer shear and differential lifting at the gust front is also thought to lead to precursor vortices for tornado development. In this case, the horizontal vorticity in the boundary layer, due to the change in strength and direction of the wind with height, is tilted into the vertical by interaction with a gust front, and then the vertical vorticity is very much intensified by vortex stretching in the vertical.

When two gust fronts from adjacent storm cells collide, they produce enhanced lifting at the region of collision, and this can be another favored location for storms to be generated.

Figure 4 Plan view of an idealized cumulonimbus system. A new cumulonimbus cell is often formed at the gust front, in a direction determined by the low-level wind and shear structure.

The regeneration of cumulonimbus storms at the gust front is an intriguing way in which the most turbulent, nonlinear, and irreducible of atmospheric flows can be understood in terms of relatively simple, coherent components.

In some cases, extremely intense downdrafts lead to downbursts and microbursts, which produce extremely intense gusts at the surface, and are a severe hazard for aircraft. Such events are hard to forecast and can result from convective clouds which, to the eye, appear relatively benign.

Sea Breezes and Other Thermally Generated Winds

The sea breeze is the best example of a flow generated by the relatively rapid generation of a baroclinic zone (a horizontal temperature or density gradient) at low levels of the atmosphere. Warming of the land surface after sunrise is rapid, while the sea surface temperature remains almost constant, so the boundary-layer inland becomes relatively warm over the space of a few hours. This leads to a 'baroclinic overturning' (Figure 5(a)) in which the warm air tends to rise and the cool air to subside, with corresponding horizontal flows to balance mass. As this circulation develops, the development of a flow resembling a density current is observed, as a cold sea breeze front pushes inland. The front may be perceived in cloud formed due to the forced ascent, or in visibility changes. Continued heating of the land surface means that there is likely to be relatively strong convective turbulence in the boundary-layer inland, which tends to dissipate the sea breeze front and render it a more diffuse baroclinic zone. However, as the surface heating

Figure 5 Baroclinic tendencies in horizontal vorticity lead to thermally driven flows; (a) the sea breeze and (b) a katabatic, downslope wind.

diminishes in the evening, the convective turbulence decays and the front may intensify and propagate further inland. Like a cold pool from a convective storm, the sea breeze front is also sensitive to the ambient winds. In strong background, winds a sea breeze will not be observed. In lighter winds, an intense sea breeze front tends to occur in conditions of light offshore flow.

A density current in the atmosphere is in a state of balance between the pressure gradient force due to the density change across the front, and drag on the current due to turbulent stresses (principally Kelvin–Helmholtz instability at the head). However, the sea breeze is also influenced by the Coriolis acceleration, over a timescale $1/f$, and can be expected to turn with the Coriolis acceleration as the day progresses. Sea breezes are quite sensitive to the large-scale flow, and will not develop if the ambient winds are strong.

After sunset it is possible for a land breeze to develop, as the land surface cools more rapidly than the sea surface. However, the ensuing surface inversion, which suppresses turbulence, does not develop as deeply as the daytime convective boundary layer, so the land breeze tends to be less active and less intense than the sea breeze.

Under conditions of light ambient winds, comparable circulations can be observed at boundaries between land surface types. These circulations are generally weaker, less coherent and harder to observe than the sea breeze, because the contrasts in surface heating between different land surface types is weaker than the land–sea contrast. However, coherent sea breeze-like circulations occur over cities (related to the ‘urban heat island’), at forest–crop boundaries, and in semiarid regions at contrasts in soil moisture. There is increasing evidence, notably from the Sahel zone of West Africa, that these circulations forced by land surface contrasts in vegetation or soil moisture influence the generation of cumulonimbus rainfall. This is an important way in which the land surface patterns exert some control on rainfall, and therefore lead to feedbacks between the slow evolution of the land surface and the rapid mesoscale processes causing rainfall. Similarly, other results from the Amazon basin have indicated that mesoscale patches of deforestation may result in increased rainfall over the deforested areas, with a consequent promotion of forest regeneration in those areas.

On sloping terrain, the diurnal cycle of surface heating leads to baroclinicity relative to the background air, and tends to cause upslope, or anabatic, flow in the daytime and downslope, katabatic, flows at night (**Figure 5(b)**). Again, these flow regimes only develop under conditions of light ambient wind, but when they do occur they may dominate the local meteorology.

Thermally generated winds can be very important to the local meteorology and climate of a specific location, influencing the daily temperatures, cloud cover, winds, and rainfall on scales of a few to hundreds of kilometers. Therefore, these mesoscale features need to be accounted for in making assessments of the weather and climate of locations where surface contrasts are strong, such as coastal regions or large cities. Accurate representation of all of these thermally generated flows in numerical models requires close attention to the surface and boundary-layer conditions,

as well as suitable model resolution to represent the mesoscale dynamics.

Synoptic Fronts

The fronts which form within synoptic cyclones exhibit lengthscales far shorter than those of the parent system, and are controlled by a spectrum of dynamical processes, so that synoptic fronts are really mesoscale features. It has been known since the early twentieth century that synoptic fronts exist primarily as a balance between the tendency for thermal overturning due to the frontal pressure gradients (with warm air tending to rise) and the Coriolis force associated with along-front geostrophic winds. Therefore, although fronts are associated with temperature contrasts primarily, they are always also associated with changes in the winds, as well as humidity and clouds changes.

The genesis of synoptic fronts is well represented in primitive equation simulations, but the genesis is best understood in SG theory, which predicts the collapse of a synoptic thermal gradient (on the scales of hundreds of kilometers, for example) to a mathematical singularity in finite time. In the atmosphere, a singularity in winds and temperatures does not occur, because the flow moves to a low Richardson number (predicted by the SG theory), at which point turbulent effects lead to mixing of the temperature and wind contrasts. Subsequent to this point, it is assumed that a real front is in a state of balance between Coriolis force, thermally derived pressure gradient forces and turbulent stresses, and observational studies have largely confirmed this state.

In addition to the interplay between balanced and turbulent forces at the front, most synoptic fronts are characterized by significant cloud and precipitation features, which can have a first-order influence on the dynamics. Cold fronts, in particular, tend to trigger cumulonimbus convection, which in turn generates strong downdrafts and cold pool/gust front structures at the surface. A number of observations of the low-level structure of active cold fronts have shown the details of the surface front to resemble a density current quite closely. Sometimes, a frontal zone is composed of a number of rainbands, aligned almost parallel to the front, whose nature can resemble that of a squall line. Rainbands have been attributed to a number of processes, such as conditional symmetric instability, which occurs when the (moist equivalent) potential vorticity becomes negative. Synoptic fronts, then, can span the range of mesoscale phenomena: they are formed out of the larger, synoptic-scale flow, and can exhibit cumulonimbus convection, rainbands, and density current structure.

One of the important features of the SG model of a synoptic front is that the system remains a continuous feature – a zone of smooth changes in the atmospheric properties – up to the time at which a mathematical singularity occurs. Since these fronts form as components of a baroclinically unstable wave (for instance, fronts appear in an SG version of the theoretical Eady wave), the front may propagate as a wavelike phenomenon, meaning that the fronts are propagating as the steep part of a wave moving through the atmosphere. For this reason, there is an important possibility of material transport through the frontal zone. This behavior is observed and has important consequences for chemical transport: a front is not a barrier to

airflow, and air may flow from one side of a front to the other (generally with a strong along-front motion also). This, in conjunction with the rapid vertical motion due to the cross-frontal circulations and the frontal cloud features, means that synoptic fronts are important agents of transport in the atmosphere.

Mesoscale Cyclones

Vortices occur on all scales in the atmosphere, and those on the mesoscale are particularly important in terms of observable weather. As ever in this regime, mesoscale vortices are formed and influenced by the whole spectrum of physical and thermodynamic processes.

Secondary cyclones commonly form on the synoptic fronts of parent cyclones. These secondaries can develop by baroclinic instability of the parent front (feeding on the frontal temperature contrasts and potential energy), but may also have a significant or even dominant component of barotropic instability, arising from the horizontal shears at the front and feeding off the frontal kinetic energy. Such systems may develop explosively and cause significant damage. The horizontal scales of these secondary cyclones range from the synoptic scales right down to scales of tens of kilometers or less.

In addition to the formation of cyclones through dynamical energy conversions, cloud processes can contribute significantly to the energetics of cyclogenesis. Equivalent static stability (defined in terms of a moist equivalent potential temperature) is generally lower than dry stability, so the growth rate of baroclinic waves in a saturated atmosphere is faster than the dry growth rate, and the lengthscale of the resulting cyclone is shorter.

Tropical cyclones, including hurricanes and typhoons, also lie within the mesoscale regime. These extreme weather systems have been the subject of a great deal of research and forecasting effort over many years, yet remain difficult to predict. Their dynamics are dependent on many processes in the atmosphere, including balance, moist convection and radiative fluxes, as well as complex ocean–atmosphere interactions. Polar lows occur in high latitudes, usually associated with rapid release of latent heat where cold air moves from the ice sheets over a relatively warm ocean, but also may derive energy from baroclinic conversions.

MCSs, which appear through self-organization of cumulonimbus convective storms, develop mesoscale cyclones in their lower levels over a period of a few hours. On the mesoscale, the strong ascent, which develops in cumulonimbus storms can lead to mesocyclones through tilting, stretching and baroclinic generation of vorticity.

It appears that mesoscale vortices can occur on all scales, and are responsible for a large number of the most severe windstorms we encounter, including tornadoes, hurricanes, and secondary midlatitude storms. In many cases, there have as yet been too few observations of such vortices to categorize them properly, and the balance between dynamic and thermodynamic energy sources for cyclogenesis across the spectrum of

scales is still not well understood: this remains a very active area of research.

Conclusions

In terms of societal impact, mesoscale meteorology encompasses some of the most important weather systems observed. Cumulonimbus storms, surface-forced mesoscale circulations, synoptic fronts, and mesoscale cyclones all produce wind, rain, and thermodynamic patterns of significant influence on society. However, by definition of this scale as one lying between the large and small scales of the atmosphere, it is generally not possible to make many simplifications in our descriptions of the physics and mathematics of these systems. This article has attempted a survey of some of the most important mesoscale phenomena, and tried to link these to the underlying physics and mathematics describing systems in different parts of the mesoscale regime. Each of these phenomena is described in more detail in other articles.

Cloud and Precipitation Bands

Synopsis

The term 'precipitation band' describes an area of precipitation that originates from updrafts that are either nonconvective or weakly convective, and is sufficiently elongated that an orientation can be assigned. Precipitation bands are common within extratropical and tropical cyclones, and also develop along topographical and geographical features, such as mountains, islands, coastlines, and lake shores. The taxonomy used to classify precipitation bands derives from radar studies of precipitation structures in various areas of the world. Precipitation bands commonly form as the result of frontogenesis, deformation flow, moist symmetric instability, boundary-layer convergence, gravity waves, topographic effects, and seeder-feeder processes.

Introduction

When viewed from satellites, large weather systems such as extratropical and tropical cyclones are often composed of clouds that organize on the mesoscale in linear features called bands. From a radar perspective, precipitation falling from these clouds also organizes along lines. Meteorologists use the term 'squall line' to describe a line where the precipitation originates from thunderstorms produced by strong convective updrafts. The term 'precipitation band' is used to describe an area of precipitation that typically originates from updrafts that are either nonconvective or weakly convective, and is sufficiently elongated that an orientation can be assigned. Precipitation bands are called 'rainbands' and 'snowbands' depending on the type of precipitation they produce. When precipitation echoes appear on radar in several long lines or bands, the weather system is said to exhibit banded structure. If bands of heavier precipitation appear within a larger field of widespread precipitation, they are often called 'embedded bands.'

The structure, intensity, and orientation of precipitation bands in extratropical cyclones are primarily related to forcing occurring along frontal zones. In tropical cyclones, rainbands outside the eyewall are related to forcing associated with the relative motion of the vortex through its environment and to inertia-gravity waves. Precipitation bands also exist far from cyclones. For example, precipitation bands can form and sometimes align along topographical features, such as mountains and islands, or can be forced by variations in surface heating, such as along coastlines or over the U.S. Great Lakes in winter. Precipitation bands organize on the mesoscale, and range in width from about 5 to 250 km, and in length from tens to over a thousand kilometers. Precipitation bands have time-scales that range from less than an hour to more than a day. These scales are usually determined by scales of the forcing mechanisms that trigger and maintain them.

Band Classification

Extratropical Cyclones

The taxonomy used to classify precipitation bands in extratropical cyclones arose primarily from studies of cyclones in coastal locations of the United States, the British Isles, and

Japan. This classification, shown in Figure 1, consists of six major band groups and is based on the physical relationship of the bands to frontal boundaries. The narrow cold frontal rainband, typically about 5 km wide, is aligned with the surface position of the cold front. On satellite images, the band often appears as a narrow ropelike cloud that can extend hundreds or even thousands of kilometers along the surface cold front. Updrafts associated with forced convection can exceed 5 m s^{-1} within the band, and locally heavy rain can occur as the band passes. From a radar perspective, the narrow cold frontal rainband often consists of small ellipsoidal cores of heavier rainfall oriented about $30\text{--}35^\circ$ to the cold front, separated by gaps of lighter rainfall. These regularly spaced precipitation cores and gaps are believed to develop as a result of horizontal shearing

instability associated with strong wind shear across the frontal interface. Occasionally, the updrafts in the precipitation cores have been shown to produce weak tornadoes. Wide cold frontal rainbands develop behind the surface cold front. These bands, which form within the warm air rising along and over the frontal surface, are about 50 km wide and are parallel to the front. The updrafts in these bands are generally much weaker than the narrow cold frontal rainband, on the order of 0.5 m s^{-1} or less. Warm frontal rainbands have similar physical characteristics as wide cold frontal rainbands, except that they develop north of the surface warm front, as warm air from the south overruns and rises over the cold air. They are typically parallel to the surface warm front, are often embedded in lighter precipitation, and have updrafts with magnitudes similar to wide cold frontal rainbands.

Mature oceanic and continental cyclones often appear as well-defined comma-shaped cloud patterns on satellite pictures. These comma-shaped cloud patterns are characterized by a sharp boundary aloft between cool, dry air subsiding from the upper troposphere and moist air rising from the lower troposphere. This boundary, which appears on infrared satellite images as a sharp line demarking high and shallow or sometimes no clouds (e.g., [Figure 2](#)), typically occurs ahead (east) of the surface cold front and has been described in meteorological literature as an overrunning upper-level cold front, a prefrontal cold surge, a cold front aloft, or as a split front. The dry air behind this boundary is called the dry slot. The passage of the upper-level front is characterized by a sharp drop in equivalent or wet-bulb potential temperature, which is always associated with a sharp reduction in relative humidity and sometimes with a reduction in temperature. The organization of precipitation ahead of the upper-level front (at the leading edge of the dry slot) depends on the stability and vertical wind shear in the moist air ahead of the front. In oceanic and cold season continental cyclones, a rainband called the prefrontal cold surge rainband or cold front aloft rainband, typically develops along or slightly ahead of this boundary ([Figure 2\(a\)](#)). This rainband can extend hundreds of kilometers. In warm season continental cyclones, the moist air ahead of the front is often unstable and the vertical shear may be significant. In these cases, a squall line or a line of supercell thunderstorms may be triggered ahead of the upper-level cold front ([Figure 2\(b\)](#)). Convection, organized in bands, can also develop behind the upper-level cold front, where enhanced radiation (due to the dry, cloud free air aloft within the dry slot), along with moist low-level surface air can create extreme thermodynamic instability.

A wide band of precipitation typically wraps around the northwest quadrant of the low-pressure center of mature cyclones ([Figure 3](#)). In continental winter cyclones, this band often produces moderate to heavy snowfall, and is responsible for major winter storms and blizzard conditions. Smaller bands of heavier snowfall, often aligned along the midtropospheric thermal wind, are sometimes embedded within the broader wrap-around precipitation region. As a cyclone decays, the band typically elongates and narrows under the influence of background deformation flow.

All of the bands described above occur within the general envelope of clouds that compose the cyclone's comma-cloud pattern. With the exception of the narrow cold frontal

Areas of cold (warm) advection are indicated as cross-isobaric flow toward high (low) pressure. On each panel, a precipitation band appears at the leading edge of the cold air advection marking the position of the upper-level cold front (see arrows).

rainband, these bands are general enhancements of stratiform precipitation that characterizes the comma-cloud pattern. Bands also occur in the cyclone's warm sector, ahead of the primary cyclone cloud pattern. When they occur, these bands are called warm sector rainbands. Bands well behind the surface cold front are called post-cold frontal rainbands.

Tropical Cyclones

Concentric and spiral bands of clouds and precipitation are among the most striking features of a mature tropical cyclone. The classification of precipitation bands in tropical cyclones, shown in [Figure 4](#), has been developed primarily from studies of hurricanes over the North Atlantic Ocean. In some tropical cyclones, particularly intense hurricanes, precipitation inside

The dynamics of the tropical hurricane core. *Aus. Meteor. Mag.*, 36, 183–191. Commonwealth of Australia copyright, reproduced with permission.

a radius of about 100 km from the vortex center tends to be axisymmetric, with convection organized in one or more concentric rings. These rings, called the outer and inner eyewalls, contract toward the center of the vortex as a hurricane

intensifies. With time, the outer ring replaces the inner ring, leading to cyclic changes in central pressure. Precipitation organizes in spiral rainbands outside the radius of the outer eyewall in stronger hurricanes, and sometimes into the eyewall radius in weaker tropical cyclones. Unlike the concentric eyewall rainbands, precipitation in the outer spiral bands can be either stratiform or convective in nature. A large rainband, called the principal band, often extends from near the radius of the outer eyewall to the outer radius of the hurricane cloud pattern. This band normally occurs on the east side of a cyclone. The principal band typically has cellular convection along its axis, a clear region along its concave side, and stratiform precipitation falling from an anvil-like feature on its outer side. Other bands, called secondary bands, are found on either side of the principal band. These typically contain shallow convection and vary significantly in intensity. Sometimes short rainbands, called connecting bands, are present between the principal and secondary bands. A distinct connecting band often joins the principal band to the eyewall. This band either contains stratiform precipitation or weak convection. These bands together are termed the stationary band complex, since they move slowly, if at all, relative to the vortex. Tropical storms also contain smaller-scale banded precipitation features that propagate outward relative to the vortex.

Mechanisms Leading to the Formation of Banded Features

Extratropical Cyclones

Several mechanisms have been advanced to explain the existence of banded precipitation regions within extratropical cyclones. These include frontal lifting and/or frontogenetic circulations, moist symmetric instability (MSI), boundary layer convergence, gravity waves, topographic effects, and seeder-feeder processes. While it is difficult to generalize which of these mechanisms will explain the formation of a specific

precipitation band, there is considerable evidence that the aforementioned mechanisms are among the most important ones.

Frontogenesis

Banded features in extratropical cyclones are associated with vertical circulations organized along lines. Frontogenesis, a primary forcing mechanism for these vertical motions, is the process by which the thermal and moisture gradients between air masses are concentrated into narrow zones called fronts. During frontogenesis, cloud and precipitation producing transverse vertical circulations are generated, with ascending motion, concentrated into a quasi-linear narrow zone parallel to a front, on the warm side of the front. Frontogenetic circulations have been studied using quasi-geostrophic and semi-geostrophic theory, two of a hierarchy of approximations to the fundamental governing equations. The most realistic of these theories uses the semi-geostrophic system of equations, with inclusion of latent heat release to simulate the effects of condensation. From a quasi-geostrophic perspective, the intensification of the cross-front thermal gradient by background geostrophic deformation, leading to warm and cold advection on opposite sides of the front, destroys the thermal wind equilibrium. The atmosphere tries to restore the thermal wind equilibrium by generating a secondary circulation that produces vertical and ageostrophic motions that counter the effects of frontogenesis. During this process, adiabatic cooling is generated by the rising motion on the warm side, and adiabatic warming is produced by the sinking motion on the cold side of the front, partially negating the effects of frontogenesis. Semi-geostrophic theory takes into account the characteristically different length and velocity scales in the along- and cross-front directions by including the effects of thermal advection by the ageostrophic flow, which are ignored by quasi-geostrophic theory. In addition, the inclusion of moisture in the semi-geostrophic equations accounts for effects of latent heating associated with condensation on the warm side of the front. The resulting semi-geostrophic frontal circulations include a more intense, narrow sloped updraft on the warm side of the front (Figure 5), a frontal surface that tilts in the vertical toward the cold air, and a stronger thermal gradient near the surface than in quasi-geostrophic theory. The orientation, scale, and vertical motions associated with certain rainbands found in the vicinity of fronts qualitatively match these theoretical predictions.

Boundary layer convergence

The most prominent example of rainbands associated with boundary layer convergence is the narrow cold frontal rainband. Under the influence of deformation flow and the accompanying frontogenesis, the thermal gradient at a cold front sometimes collapses to a near-discontinuity at the surface. When this collapse occurs, the air behind the cold front takes on characteristics of a density current, and strong localized convergence occurs at the front. A sharp narrow updraft develops in the warm air ahead of the front as the warm air rises over the advancing density current. The resulting rainband, the narrow cold frontal rainband discussed above, often contains updrafts exceeding several meters per second and produces locally heavy rain. Studies of the narrow cold frontal rainband

Figure 5 Ageostrophic stream function about a front obtained by solving the semi-geostrophic Sawyer–Eliassen equation for a case of deformation forcing under moist conditions. Height and distance (x) are expressed in nondimensional units. From Emanuel, K.A., 1985. Frontal circulations in the presence of small, moist symmetric stability. *Journal of Atmospheric Sciences* 42, 1062–1071; reprinted with permission from the American Meteorological Society.

in oceanic regions have shown that the warm air lifted by the density current is often stable or very slightly unstable, indicating that the updrafts are forced rather than due to free convection. The depth of the updrafts is limited to the depth of the forced ascent, usually no more than 3–5 km. The updrafts in the narrow cold frontal rainband are often complicated by small vortices that form along the wind-shift line associated with the advancing density current. Shearing instability is believed to be the principal mechanism for the formation of such vortices. The updrafts then organize in discrete precipitation cores, separated by gaps. Narrow cold frontal rainbands are not as common in continental cyclones as they are in oceanic cyclones, probably because the air ahead of cold fronts is more likely to be potentially unstable and, when lifted, produce squall lines or other deep convective phenomena.

Ducted gravity waves

Gravity waves are buoyancy oscillations in a stably stratified fluid where the restoring force is gravity. Gravity waves are ubiquitous in the atmosphere, but most are not large enough in amplitude to trigger precipitation bands. This is true because atmospheric gravity waves are highly dispersive, propagating vertically and rapidly losing their energy to the upper atmosphere. As a result, gravity waves normally cannot travel very far from their source before they no longer have sufficient energy to lift air to the lifting condensation level and trigger clouds and precipitation. A particular class of gravity waves, termed *ducted gravity waves* because their energy is trapped in an atmospheric duct, has been associated with precipitation bands. Ducted gravity waves require very specific conditions that include (1) a sufficiently deep low-level stable layer that can accommodate a quarter vertical wavelength of the wave, (2) a deep moist neutral layer above the stable layer, and (3) a critical level above the stable layer, where the mean wind speed in the direction of propagation equals the wave phase speed. These conditions most commonly occur north of warm fronts associated with cyclones, but have been observed in other

environments. When these conditions exist, theory predicts that wave energy will be trapped within the duct, thus allowing the wave to propagate long distances. If the wave amplitude is sufficiently large, the vertical motion induced by the wave can be sufficient to trigger a precipitation band. For rainbands to occur, the atmosphere above the stable layer must be near saturation, a common condition over warm frontal surfaces. The structure of a propagating ducted gravity wave is shown in **Figure 6**. The location of greatest rising motion, where a precipitation band would be triggered, is a quarter of a wavelength upstream from the location of lowest pressure. Observations of precipitation bands in conditions where ducting is favorable often show this relationship in surface precipitation and pressure traces, suggesting that these bands may be forced by ducted gravity waves.

Moist symmetric instability

MSI is a two-dimensional, semigeostrophic mesoscale instability in which both gravitational and inertial body forces determine the stability of a displaced air parcel. The term symmetric refers to a basic state and resulting circulations that do not vary in a particular horizontal direction, e.g., along a baroclinic zone. In the Northern Hemisphere, the condition for inviscid, inertial instability is $\partial m_g / \partial x < 0$, where $m_g = v_g + fx$ is the geostrophic absolute momentum, v_g is the geostrophic wind in the direction perpendicular to the temperature gradient, f is the Coriolis parameter, and x is the cross-front distance, increasing toward warmer air. The condition for conditional instability is that $d\theta_{ev}^* / dz < 0$ at a level where $\Gamma_m < -dT_v / dz < \Gamma_d$. Here θ_{ev}^* is the saturation virtual equivalent potential temperature, T_v is the virtual temperature, and Γ_m and Γ_d are, respectively, the moist and dry adiabatic lapse rates. In an atmosphere where the lapse rate of θ_{ev}^* is negative when evaluated along a surface of constant m_g , a saturated air parcel can be inertially stable to horizontal displacements ($\partial m_g / \partial x > 0$) and gravitationally stable to vertical displacements ($d\theta_{ev}^* / dz > 0$), but unstable with respect to slantwise displacements. The release of this instability, termed *conditional symmetric instability*, has been suggested as a mechanism for the development of banded structure in frontal precipitation. In situations where the atmosphere is unsaturated,

Figure 6 Idealized vertical cross section of a linear plane gravity wave with no base current, propagating to the right at speed c . The heavy sinusoidal line is a representative isentropic surface or a temperature inversion. Surface pressure extrema are labeled H and L, while cold and warm temperature anomalies are denoted by K and W, respectively. From Bosart, L.F., Sanders, F., 1986. Mesoscale structure in the megapolitan snowstorm of 11-12 February 1983. Part III: a large amplitude gravity wave. *J. Atmos. Sci.*, 43, 924-939; reprinted with permission from the American Meteorological Society.

but may be brought to saturation by lifting (for example, during frontogenesis), the potential for slantwise instability to occur can be evaluated by identifying regions where the gradient of the virtual equivalent potential temperature along an m_g surface, $d\theta_{ev}^* / dz|_{m_g} \leq 0$. This condition is identical to the equivalent potential vorticity being negative. Potential and conditional symmetric instability are both types of MSI. Bands associated with MSI are aligned along the thermal wind, move with the environmental flow, and have spacing that is related to both the depth of the unstable layer and the slope of the moist isentropes. **Figure 7** shows a schematic cross section through an environment susceptible to MSI. The slantwise ascent within the bands occurs between the slope of the m_g and θ_{ev}^* surfaces. Observations in regions of banded precipitation in frontal systems have often found that $d\theta_{ev}^* / dz|_{m_g} \approx 0$, suggesting that the atmosphere may have undergone symmetric overturning, reaching a state of moist slantwise neutrality.

Seeder-feeder processes

The seeder-feeder mechanism is a combined dynamical-microphysical mechanism for organizing ice crystal plumes into banded structures. The 'seeder' component consists of elevated convection, called generating cells, near the cloud top region that creates ice particle plumes (**Figure 8**). The 'feeder' component results from broad scale ascent and moisture convergence in the lower part of the cloud, typically associated with frontogenesis. Deformation associated with frontogenesis may organize the hydrometeor plumes to produce linear banded features. Together these provide conditions for the ice particles to nucleate, grow to become snowflakes or raindrops, and organize into linear bands.

Tropical Cyclones

Tropical cyclones can be considered dynamically to consist of two distinct regions, an inner core where accelerations due to

Figure 7 Idealized example of a vertical cross section in the Northern Hemisphere, normal to the thermal wind vector, showing surfaces of constant m_g (solid lines), saturation virtual equivalent potential temperature, θ_{ev}^* . In this example, θ_{ev}^* increases with height (conditional stability), m_g increases with increasing x (inertial stability). The lifting condensation level, level of free slantwise convection, and level of neutral buoyancy are denoted by LCL, LFS, and LNB, respectively.

Figure 8 Radar data from the comma-head region of an extratropical cyclone showing precipitation streamers from 'seeder' generating cells near cloud top merging and increasing in intensity as they descend lower into the cloud into the 'feeder' zone.

relative rotation dominate over the Coriolis force, and an outer region where the Coriolis force is comparable to rotation in influencing storm dynamics. As a result, in the inner gyre the air trajectories form closed paths, whereas in the outer region they do not. The boundary between these regimes appears to be the boundary between bands that appear as concentric rings, such as the eyewall, and outer bands, composed of a stationary band complex and moving convective spiral bands. The location of the boundary between these two regimes varies with hurricane strength, so the stationary band complex tends to occur nearer the center of weaker hurricanes and on the peripheries of stronger hurricanes.

Analyses of hurricane structure obtained from aircraft penetrations suggest that the principal band lies along the flow streamline separating two distinct regions of the storm. On the concave, or inner side of the principal band, moist high θ_e air lies within the closed vortex circulation of the hurricane and orbits the center several times during its residence time within the vortex (see Figure 9). On the convex outside of the principal band, somewhat drier lower θ_e environmental air remains in the vortex circulation for less time than that required to orbit the center once. The principal band develops as a result of the relative motion of the vortex through its environment. In the environment of low-level easterly winds, the relative motion of the vortex leads to a region of concentrated low-level convergence along the streamline where environmental flow encounters the rotating flow within the vortex. Connecting bands generally have stratiform characteristics, although they may contain shallow convection. A stratiform band will result if a plume of ice particles originating from the eyewall falls through the 0°C level after spiraling outward at upper levels of the storm. The connecting bands in hurricanes generally sharply cross low-level streamlines, suggesting that they arise from this process.

Propagating bands also exist in tropical storms. Some bands propagate outward from the core vortex. These bands are thought to be associated with vortex Rossby waves or mixed

Figure 9 Schematic representation of the stationary band complex of a tropical cyclone, the bands that compose the complex, and the flow in which the complex is embedded. From Willoughby, H.E., Marks Jr., F.D., Feinberg, R.J., 1984. Stationary and moving convective bands in hurricanes. *Journal of Atmospheric Sciences* 41, 3189–3211; reproduced with permission from the American Meteorological Society.

Rossby waves and gravity waves. Some radiating gravity waves are believed to be generated during oscillations of the storm track, although stationary tropical cyclones are known to be capable of radiating gravity waves and rainbands. Track oscillations are thought to be excited both when tropical storms encounter land and by normal-mode oscillations of the hurricane vortex. There are also inward propagating rainbands, which likely form due to low-level convergence. Inward

propagating rainbands sometimes result in secondary eyewall formation as an outer rainband contracts into a closed circular band surrounding the primary eyewall and eventually contracts and replaces the inner eyewall as the inner eyewall contracts and dissipates.

Other Precipitation Bands

Although precipitation bands most commonly appear in extratropical and tropical cyclones, they also develop outside these circulations, primarily forced by variations in topography and surface conditions. Flow over or around topographic features, such as a mountain range or an island, can create elongated zones of convergence and vertical motion that create precipitation bands. For example, the Island of Hawaii, which consists of two volcanic mountains exceeding 4000 m elevation, lies in the northeasterly trade wind regime of the North Pacific Ocean. As the trade winds encounter Hawaii, they are unable to flow over the island because of an inversion at the top of the trade wind layer and must, instead, flow around the island. At night, cool drainage flow originating in the higher elevations of the island often flows offshore on the east (upwind) side of the island and meets the incoming trade winds. The boundary between the drainage flow and the trade winds leads to a persistent zone of convergence, which forces vertical motion, clouds, and precipitation. The deformation of the trade wind flow around the island organizes the precipitation into rainbands that align approximately parallel the shoreline, as shown in Figure 10.

Figure 10 Radar reflectivity on 3 August 1990, measured by a radar located along the northeast shore of the island of Hawaii, showing a rainband located just offshore of the island.

Variations in surface properties can also lead to the formation of precipitation bands. In fall and winter months, when cold, arctic air masses move across warmer water bodies such as the Great Lakes, lake-effect snowstorms may occur. Under suitable conditions of lake–air temperature difference, wind speed and direction, extent of fetch over the lake, and environmental stability upstream of the lake, strong organized convective precipitation bands may develop. Specifically, three morphological types of precipitation bands have been identified to occur over the Great Lakes in wintertime. They are wind parallel bands, shoreline bands, and midlake bands. For example, when air over the lake is very cold, and winds are either weak or parallel to the long axis of the lake, a long precipitation band will sometimes develop near the center of a lake approximately parallel to the lake's shores (Figure 11). This band develops as a result of a land breeze circulation between the lake and its shorelines. Air residing over the lake, heated by the warm lake surface, becomes unstable and rises. Cooler air flows inward from both shorelines to replace the rising air. The air from shore, in turn, is heated as it flows over the lake. A circulation develops with air flowing inward over the lake, rising in a narrow zone at the lake center, and returning shoreward aloft while slowly descending. On the other hand, shoreline bands, which are usually weaker than midlake bands, develop along or close to the shoreline of a lake, when winds have a cross-lake component. Such lake-effect snowbands have been shown to result in locally heavy snowstorms in the lee of the lakes.

Other local topographic and geographic features, such as mountains, shorelines, islands, and bays, frequently induce vertical motions organized along lines. The precipitation bands that form often have characteristics unique to the specific region, but can have a significant local impact on rain or snowfall.

Figure 11 Radar reflectivity on 7 March 1996, measured by the WSR-88D radar located in Romeoville, Illinois. A lake-effect snowband extends down the center of Lake Michigan and onto the southern shoreline.

Introduction

Evaporation of rain within a thunderstorm produces a ground-based pool of cold air that spreads under its own weight and thereby generates gusty surface winds. The leading edge of the spreading cold pool is therefore known as the ‘gust front’. The gust front is an example of a ‘density current’ (see **Mesoscale Meteorology**: Density Currents), a phenomenon that occurs in a great variety of geophysical and engineering applications. As a characteristic feature of thunderstorms, the gust front plays a role in other aspects of thunderstorms, such as storm cell redevelopment (see **Mesoscale Meteorology**: Severe Storms).

The basic phenomenon of cold air spreading beneath a thunderstorm has been recognized in writing since the early nineteenth century. However, the term ‘gust front’ started to appear in the literature only in the early 1960s. Before that time the phenomenon was variously referred to as the pressure jump line, squall front, micro cold front, or outflow boundary, among other designations; the latter two are still used frequently.

Physics

Evaporation of Rain

Choosing the simplest case to illustrate the basic physics, imagine a vertically erect thunderstorm with rain falling through it (**Figure 1**); since the air beneath the thunderstorm is subsaturated, rain falling into it may evaporate and thereby cool the subcloud layer. Considering an isobaric process in which the rain evaporates until the subcloud layer is saturated, the first law of thermodynamics gives [1].

$$T_f - T_i = -\frac{L}{c_p} [q_{vs}(T_f) - q_{vi}] \quad [1]$$

Here T_i and q_{vi} are the initial temperature and water vapor mixing ratio (mass of water vapor per unit mass of dry air) of the subcloud layer, respectively, T_f is final temperature at saturation, and q_{vs} is the saturation mixing ratio; the latent heat of vaporization $L = 2.5 \times 10^6 \text{ J kg}^{-1}$ and $c_p = 1006 \text{ J kg}^{-1} \text{ K}^{-1}$ is the heat capacity for dry air at constant pressure (the effect of water vapor on the heat capacity has been ignored). The saturation mixing ratio is related to the pressure p and saturation vapor pressure $e_v(T)$ through eqn [2].

$$q_{vs} = \frac{R_d}{R_v} \frac{e_v}{p - e_v} \approx \varepsilon \frac{e_v}{p} \quad [2]$$

Here $\varepsilon \equiv R_d/R_v$, and $R_d = 287 \text{ J kg}^{-1} \text{ K}^{-1}$ and $R_v = 462 \text{ J kg}^{-1} \text{ K}^{-1}$ are the gas constants for dry air and water vapor, respectively. To obtain an explicit formula for T_f , one can expand q_{vs} in a Taylor series as in eqn [3].

Figure 1 Schematic diagram of a rain shaft below a thunderstorm. Evaporative cooling and weight of rain produce negative buoyancy and hence negative circulation C on the circuit shown (adopting the convention that the line element $\mathbf{l}$ on the circuit points in the clockwise direction).

$$q_{vs}(T) \approx q_{vs}(T_i) + \left. \frac{dq_{vs}}{dT} \right|_{T=T_i} (T - T_i) \quad [3]$$

Using the second part of eqn [2] to calculate the derivative in eqn [3], and then substituting for de_v/dT from the Clausius–Clapeyron equation, yields eqn [4] where RH_i is the initial subcloud relative humidity.

$$T_f - T_i = -\frac{(L/c_p)q_{vs}(T_i)(1 - RH_i)}{1 + \frac{L}{c_p} \frac{Lq_{vs}(T_i)}{R_v T_i^2}} \quad [4]$$

With typical subcloud values of $p = 900 \text{ hPa}$, $T_i = 293 \text{ K}$, and $RH_i = 0.7$, eqn [4] gives $T_f - T_i \approx -3.5 \text{ K}$. While this is not untypical of observed values, $T_f - T_i \sim -10 \text{ K}$ can be obtained in situations more complex than that depicted in **Figure 1**. For example, if drier mid-level air is entrained into the thunderstorm, RH_i in eqn [4] can be much smaller, and so $T_f - T_i$ is much lower. In any case, the basic idea expressed in eqn [4] is the same: evaporation of rain produces colder temperatures at low altitude in a thunderstorm.

Generation of Motion

Fluid motion is governed by Newton’s second law, expressed as in eqn [5], where u is the velocity, p the pressure, and ρ the

density of the fluid mixture of dry air and water substance; $-\rho g$ is the external body force (per unit volume) due to the Earth's gravity, and d/dt is the substantial derivative.

$$\frac{du}{dt} = -\frac{1}{\rho}\nabla p - g \quad [5]$$

Since we are dealing with a fluid mixture of compressible gas and liquid, we begin our development by recasting the first term on the right-hand side of eqn [5] as eqn [6].

$$-\frac{1}{\rho}\nabla p = -c_p\theta\frac{1+\varepsilon^{-1}q_v}{1+q_v+q_l}\nabla\pi \approx -c_p\theta[1+0.61q_v-q_l]\nabla\pi \quad [6]$$

Here $\pi = (p/p_{00})^{R_d/c_p}$ (p_{00} is a reference pressure), the potential temperature $\theta = T\pi^{-2}$, and q_l is the mixing ratio of liquid water; the perfect gas law $p = \rho_d R_d T + \rho_v R_v T$ and the fact that $\rho = \rho_d + \rho_v + \rho_l$ have been used. The second part of eqn [6] is an approximation based on the typical smallness of the water substance mixing ratios.

For clarity of exposition, imagine that the subcloud air shown in Figure 1 is initially motionless, although rain has fallen into it; the gust front originates with the circulation $C(= \oint \mathbf{u} \cdot d\mathbf{l})$ created around the circuit shown. From eqns [5] and [6] one can derive eqn [7] for C

$$\frac{dC}{dt} = \oint -c_p\theta[1+0.61q_v-q_l]d\pi \quad [7]$$

Considering as a reference a rain-free ($q_{l0} = 0$) atmosphere with constant $\theta_{v0} (= \theta_0 + 0.61q_{v0})$ in hydrostatic balance ($d\pi_0/dz = -g/c_p\theta_{v0}$), and expressing the dependent variables as the reference state value plus a small deviation, eqn [7] may be approximated as eqn [8].

$$\frac{dC}{dt} = \oint g \left[\frac{\theta'}{\theta_0} + 0.61q'_v - q'_l \right] dz \quad [8]$$

The prime denotes the deviation from the reference state, and terms involving products of water substance mixing ratios have been neglected. The integrand of eqn [8] is the buoyancy and is composed of three terms. The first term is the thermal buoyancy, which in the case under discussion is negative since $\theta' \approx T'\pi_0^{-1}$ and, as previously demonstrated, evaporative cooling produces $T' < 0$. The second term represents the contribution to buoyancy by the presence of water vapor which, being lighter than air, increases the buoyancy when $q'_v > 0$ (as it is in the present case). (Negative thermal buoyancy produced by evaporation of rain is numerically much greater than the offsetting effect on positive buoyancy of the accompanying increase in water vapor.) The third term represents the downward force that liquid water exerts on the air in which it resides. Although the negative buoyancy associated with rain-water loading can be significant (e.g., the negative buoyancy associated with $q_l = 10 \text{ g kg}^{-1}$ is approximately equivalent to that associated with $\theta' \approx -3 \text{ K}$), in most cases thermal buoyancy dominates.

The foregoing is simply a precise way of saying that cold, rainy air sinks and spreads out along the ground. Understanding exactly how it does so requires a model.

Models of Motion

The simplest model is to consider the initial volume of cold air as a rectangle (with unit breadth into the page) that retains its

rectangular shape as it spreads. The model predicts that at late time the front speed decreases as $t^{-1/3}$, while the height decreases as $t^{-2/3}$. However, observations (Figure 2) indicate that outflows from thunderstorms move with roughly constant speed and height.

A more sophisticated model can be obtained by considering the atmosphere as composed of two fluid layers of different potential temperatures, and using the hydrostatic approximation throughout (see Mesoscale Meteorology: Density Currents). With these assumptions, and restricting attention to motion in the x - z plane, the full x -momentum eqn [5] may be reduced to the so-called shallow water momentum equation (eqn [9]).

$$\partial_t u + u\partial_x u + g'\partial_x h = 0 \quad [9]$$

The equation expressing conservation of mass becomes eqn [10], where h and u are, respectively, the depth and horizontal speed of the cold air with potential temperature θ_0 spreading into an environment with $\theta = \theta_1$; $g' \equiv g\theta_0^{-1}(\theta_1 - \theta_0)$ is the reduced gravity.

$$\partial_t h + u\partial_x h + h\partial_x u = 0 \quad [10]$$

Using the method of characteristics, the solution of eqns [9] and [10] for the so-called 'dam-break' problem was obtained in the nineteenth century and is depicted in Figure 3(a). These solutions are characterized by a wave of depression moving into the initial reservoir and a constant speed outflow with depth falling to zero. Observations and laboratory tests of the model predictions failed to show the predicted time-varying parabolic shape near the leading edge, but rather a zone of nearly constant height falling abruptly to zero, as shown in Figure 2 and depicted in Figure 3(b). Recognizing this deficiency, researchers in the early 1960s solved eqns [9] and [10] with the condition of eqn [11] instead of $h \rightarrow 0$ at the front.

$$u_f = k\sqrt{g'h_f} \quad [11]$$

The constant k was left to be determined empirically. For $k \geq 1$, eqn [11] produces solutions exhibiting a zone of constant state behind the leading edge, in which u_f and h_f are given by eqn [12], where h_0 is the initial reservoir height (Figure 3(b)).

Figure 2 Schematic diagram of a gust front based on observations. Reproduced from Simpson (1997) Gravity Currents in the Environment and the Laboratory, 2nd edn. Cambridge, UK: Cambridge University Press.

Figure 3 Models of the gust front based on the ‘dam-break’ problem with (a) $h \rightarrow 0$ or (b) $u_f = k\sqrt{g'h_0}$ at $x = x_f$. The dashed line indicates the original position of the dense rain-cooled air; x_d and h_0 indicate, respectively, the position of the edge (i.e., the ‘dam’) and the height of the rain-cooled air; and h_d is the height of the outflow at the dam site. Reproduced from Klemp J, Rotunno R, and Skamarock WC (1994) On the dynamics of gravity currents in a channel. *Journal of Fluid Mechanics* 269: 169–198.

$$u_f = \frac{2}{2+k} \sqrt{g'h_0} \quad [12]$$

$$h_f = h_0 \left(\frac{2k}{2+k} \right)^2$$

Although these solutions have the observed features of constant (u_f , h_f) behind the front, one has no way of determining k from eqns [9] and [10]. To make such a determination, one has to return to the full x -momentum eqn [5].

The reason why the simple solution shown in Figure 3(a) is not realized in a two-layer fluid is that Kelvin–Helmholtz instability produces a nontrivial coupling between the cold pool and the environment into which it spreads. Although the details of the instability and turbulence at the interface are hopelessly complicated, one can deduce the relation between u_f and h_f from a simple control volume analysis. Taking as an observational fact that a dense fluid of height $H (= h_f)$ moves steadily at speed $U (= u_f)$ into an environment of less dense fluid in a channel of depth d (Figure 4), one can deduce eqn [13] from the vertically integrated x -momentum equation along with mass conservation.

$$\frac{U}{\sqrt{g'H}} = \sqrt{\frac{2(1-\alpha)(1-0.5\alpha)}{1+\alpha}} = k \quad [13]$$

$$\alpha = \frac{H}{d}$$

(The restriction of the flow to the finite depth d is an attempt to account for the effect of a stable layer located above the generally constant θ air in the subcloud layer.) The steady flow depicted in Figure 4, and described by eqn [13], is generally known as a ‘density current’ (or ‘gravity current’), and occurs in a wide range of geophysical and engineering problems (see *Mesoscale Meteorology: Density Currents*). With the parameter k determined by eqn [13], eqn [12] now expresses the motion in terms of the external parameters of the problem.

Figure 4 Moving at the constant density current speed U , a control volume analysis of the mass and momentum equations can be done to derive eqn [13], which relates U to H , d and $g' \equiv g\theta_0^{-1}(\theta_1 - \theta_0)$. Reproduced from Klemp J, Rotunno R, and Skamarock WC (1994) On the dynamics of gravity currents in a channel. *Journal of Fluid Mechanics* 269: 169–198.

The connection described here between the production of buoyancy, circulation, and cold outflow constitutes the minimal model for understanding the origin and nature of gust fronts. Neglected, but potentially important for quantitative prediction, are the effects of surface friction, environmental stratification, and time dependence of the buoyancy source.

Influence of the Gust Front

In addition to bringing relief from the heat of the day, the cold outflow from a thunderstorm displaces air in its path upward (Figure 2) and so may regenerate a new thunderstorm cell. Experience and models have shown that the regenerated cells occur in a preferred compass direction if the prevailing wind increases with height. So, for example, if the prevailing westerly wind increases with height, the gust front from a thunderstorm produces a new cell on its east side; a collection of such cells in close proximity, all regenerating cells on their east side, will soon give the system of cells the appearance of a line running north–south. The latter is termed a squall line. Since the squall line by its nature lives much longer than its constituent cells, these systems are the producers of copious rain, and frequently, severe weather such as flash floods, tornadoes and other high wind phenomena.

Synopsis

Hail forms as ice particles collect and freeze supercooled water drops within clouds, at temperatures below freezing. The primary variables that control growth rate are the content of supercooled liquid water within clouds and the terminal velocities of the hailstones, and the ultimate hailstone sizes at the ground depend upon the updraft velocities they encounter while growing and, again, their terminal fall speeds. They form primarily in the more severe thunderstorms, which are often quite turbulent, and consequently they encounter complicated successions of growth environments. They often have several growth layers that reflect changes of the liquid water content and temperature in their environment. Small hailstones usually are approximately spherical but may be soft or slushy; whereas, large hail usually is not spherical (the word 'diameter' is misleading when used to mean longest dimension) but usually has a density near that of solid ice. As a phenomenon of severe storms, large hail correlates well with tornadoes and hailstorms generally produce lightning, though lightning often occurs without hail. Hail suppression attempts by cloud seeding are carried out in several countries, and remote detection of hail by radar is recently operational in the United States.

Introduction

Hailstones are balls of ice that typically fall from cumulonimbus clouds. By convention, they must be greater than 5 mm in diameter but their composition, size, and shape are variable. The largest hailstones can have the longest dimensions of 15 cm or more.

Hailstone amounts are also highly variable, but generally the largest hailstones and the heaviest hailfalls are from the most severe storms; that is, storms with the strongest updrafts, tallest cloud tops, and largest size. Thus hail is correlated with tornadoes, and also with lightning, though many storms produce lightning with no hail at the ground. Hail is not as well correlated with flooding, which often results from long-lasting and slow-moving precipitation systems without strong updrafts that do not produce hail.

Hailstones include various amounts of air bubbles, often in layers that indicate growth stages, but when larger than about 2 cm in diameter their densities are usually within 5% of solid ice, 0.91 g cm^{-3} . However, hail may be slushy, containing significant amounts of liquid water, and, especially at small sizes, the air content may be sufficient that the hail is soft. Soft hail is distinguished from graupel (accumulations of rime on snow particles or small frozen water drops) only by size, and since nearly all hail falls through a thick layer of air above the freezing point before reaching the ground, soft hail is often slushy, from partial melting, when it falls. Much rainfall from cumulonimbus clouds in temperate climates is melted graupel and small hail.

Fundamental Concepts of Hail Formation

Hail forms by the accretion of water droplets onto ice particles falling through supercooled cloud. The basic elements

needed for understanding the principles of hail formation are as follows.

The Updraft and Its Consequences

Humid air rising in the cores of cumulus clouds cools as it rises. The cooling causes the condensation and growth of water droplets, forming visible cloud. The droplets supercool when the temperature falls below the freezing point. These water droplets are very small, and rise in the updraft almost as fast as the air rises, typically several tens of meters per second in hailstorms, because their terminal fall speeds are less than 10 cm s^{-1} . An ice particle big enough to have a higher terminal fall speed, within such an updraft, collides with and collects the supercooled droplets, which freeze upon impact and stick to it. This accretion is the basic mechanism of hailstone growth. The initiating particle may be a snow crystal, a snowflake, or a frozen water drop. The other main role of the updraft in hail formation is to be strong enough and long lasting enough to hold the hailstones aloft, within supercooled cloud above the freezing level, long enough to grow to their final sizes. If they are to reach the ground as hail, they must then be big enough not to melt on the way down.

Terminal velocities of hailstones are described by

$$V_T = \{(4g\rho_i D/3C_D\rho_a)\}^{1/2} \quad [1]$$

where C_D is the drag coefficient, a dimensionless quantity that expresses how the drag force (the air resistance) relates to the velocity and the fluid properties. The densities of ice and air are indicated by ρ , g is the acceleration due to gravity, and D is the diameter of the hailstone. Numerical values are plotted in [Figure 1](#), for different values of C_D and, with $C_D = 0.55$, for both sea level and 500 mb pressure. Pressure of 500 mb corresponds very roughly to -10°C and 6 km above sea level, with considerable variability depending upon local conditions.

Figure 1 Terminal fall velocities of spherical hailstones plotted against diameter, for the drag coefficients (C_D) indicated, calculated for a pressure of 500 mb (50 kPa, about 6 km above sea level) and a hailstone density of 0.9 g cm^{-3} , except where otherwise indicated. From Knight, C.A., Knight, N.C., 2001. Hailstorms. In: Charles A. Doswell III. (Ed.), *Severe Convective Storms*. American Meteorological Society, Boston, pp. 223–254, by permission of AMS.

The large range of values for C_D comes about because of the variability of hailstone shape, which influences fall speed considerably. Hailstone ‘diameter’ is often used, deceptively, to refer to the longest dimension. In the context of [Figure 1](#), the more appropriate meaning is the equivalent spherical diameter. A hailstone growing within an updraft may be ascending or descending, depending upon whether its terminal fall speed is less or greater than the updraft velocity.

The Thermodynamics of Hailstone Growth

Water remains in the liquid state when cooled below 0°C unless it contains a particle of a solid material, that is, an ice nucleus with the property of initiating ice. The content of ice nuclei in the atmosphere is variable, but as a rough average there might be one that acts at -20°C per liter of air and only one per many cubic meters active at -5°C . Thus clouds that are not too much colder than 0°C are often composed almost entirely of supercooled water droplets, since the droplet populations in clouds vary between about 100 and 1000 cm^{-3} . Hailstones grow within such clouds.

The droplets freeze when they collide with ice, releasing latent heat, about 80 cal g^{-1} . However, since the specific heat of water is 1 cal g^{-1} , a drop supercooled to -10°C is warmed to 0°C when only about one-eighth of it is frozen. If the remaining seven-eighths is to freeze, the rest of the latent heat must be absorbed by the environment, which in this case is the surrounding air, at -10°C . Growing hailstones are thus warmer than the surrounding air, and in extreme cases their

temperature may be 0°C and they may grow as a mixture of ice and water, called spongy hail.

Hailstone layering consists of shells with varying air bubble contents, which arise because of air temperature variations (changes in growth altitude) or cloud water content variations, which cause changes in the hailstone temperature.

Hail Falling Behavior, Shape, and Growth

Since hail grows by accreting and freezing water droplets, it grows mostly on its underside where the collisions occur. Small hailstones, falling at only $10\text{--}15 \text{ m s}^{-1}$, usually maintain a single falling orientation. This often leads to a roughly conical shape, with the growth ‘center’ on top and consecutive broadening layers beneath that constitute most of the bulk. When hailstones grow larger, the higher fall speed creates more turbulence and they tumble. Often their growth shapes are then flattened, most of the collisions occurring around a perimeter because of a rapid and symmetrical, but complicated, tumbling motion. [Figure 2](#) shows two sections through such a hailstone, illustrating the conical center that grew into a rather thick, somewhat elongated, disk. The tumbling has important consequences for shape and also for terminal fall speed and heat exchange, and it may aid in shedding any unfrozen water that otherwise might accumulate.

Hailstones larger than a few centimeters in diameter are often lumpy. When the hail grows wet with liquid water, lumps may form like icicles, from water flowing over the surface. Hailstones of this kind are seen in [Figure 3](#). The lumpy shapes often suggest aggregation of smaller hail, but sections through lumpy hail never have shown this to be the case. The lumpiness makes the tumbling more chaotic and the shapes more

Figure 2 Two slices through a large, oblate hailstone: the first, at right, perpendicular to the short axis of the stone and the second, at left, parallel to the short and the long axes. The photos were taken with a bright background, so clear ice appears white and ice with small air bubbles is darker. The hailstone grew in a constant falling orientation and developed a conical shape up to 2–3 cm in length. After that the growth was fastest around the perimeter of the flattened hailstone, due to a rapid, complicated but symmetrical, tumbling motion. Note the growth layers (shown by differing air bubble content) that signify changes in the growth environment.

Figure 3 Four hailstones greater than 5 cm in diameter that show prominent projections. These form as the hail grows while wet, with liquid water flowing over the hailstone surface, and grow in a manner similar to the formation of icicles.

complex, and also influences the fall speed by increasing the drag coefficient.

The rate of hailstone growth is expressed as

$$dD/dt = V_T WE/2\rho_i \quad [2]$$

where D is the diameter, W the cloud water content in mass per unit volume, and E the collection efficiency. $E = 1$ for the case of simple sweep-out, the collection of all water droplets in the volume of air traversed by the hailstone. In reality E is usually between roughly 0.3 and 0.8 depending upon the sizes of both the droplets and the hailstone, because some droplets in the path of the hailstone are carried around it by the airflow. **Figure 4** shows the typical range of values of growth rates as a function of hail size, for $WE = 2.5 \text{ g m}^{-3}$ and $\rho_i = 0.9 \text{ g cm}^{-3}$.

Hailstorms

The necessary and sufficient conditions for hail formation in a thunderstorm are easy to state in general terms. The storm needs to provide a strong updraft containing supercooled water droplets, as the environment for hailstone growth, and into this environment must come hailstone ‘embryos.’ These are particles of ice with terminal fall speeds of a few meters per second that can grow in a few tens of minutes into hailstones. Their growth must be fairly rapid because the growth environment may disappear as the updraft weakens (the updrafts in most thunderstorms are intermittent), or the supercooled water content of the updraft may become depleted, either by evaporation as the updraft air mixes with drier surrounding air or by conversion to many small ice particles. If the ascent rate of the potential hail embryo is too great it may be elevated out of the growth region before it grows big enough to fall as hail, or if the ascent rate is too slow it may fall out before it reaches large enough size.

Figure 4 Hailstone growth velocities, in cm min^{-1} , as a function of diameter calculated for the three top curves in **Figure 1**, assuming an effective cloud liquid water content WE of 2.5 g m^{-3} and no shedding of liquid water. Cloud water contents vary from zero to perhaps twice this value, and growth rates vary accordingly (see eqn [2]). From Knight, C.A., Knight, N.C., 2001. Hailstorms. In: Charles A. Doswell III. (Ed.), Severe Convective Storms. American Meteorological Society, Boston, pp. 223–254, by permission of AMS.

The formation of hail, then, depends upon a critical interrelation among the three-dimensional airflow within storms, the fate of the supercooled droplets that occur within the updrafts, and the trajectories of the potential hail embryos. These factors work together to determine how much of the water vapor that condenses reevaporates in the middle and upper atmosphere, how much of it falls as rain, and how much as hail. The percentage of it that falls as hail is difficult to measure, but is usually very small.

Hail in Supercell and Multicell Storms: Steady and Time-Dependent Concepts

There are at least two specific hypotheses for hail formation that refer to two idealized storm types, the supercell storm and the multicell storm. The supercell is a type of storm that can last a long time and travel considerable distances, often producing tornadoes and often producing long swaths of large, damaging hailstones. The diagrams in **Figure 5** represent a typical case in the central United States, a map view looking down at the storm and a cross-sectional view, both indicating possible growth trajectories. The humid air entering the storm comes in a vigorous flow at the surface from the south or southeast, rises up through the middle of the storm, and exits to the east because the flow in the upper levels is from the west, that carries the southern part of the outflow in the upper levels over the top of the inflowing air at the surface. The updraft in the central part of the storm can be $30\text{--}50 \text{ m s}^{-1}$, so small ice particles that grow within the updraft do not have time to grow very large and attain much fall speed before being ejected into the outflow at the top of the storm, producing the extensive anvils characteristic of supercells. However, in the outflow there is little vertical air motion, and the idea is that some of these particles fall back into the inflow at low levels. They may

Figure 5 Schematic of airflow and some hydrometeor trajectories deduced in a supercell storm. (a) Plan view, looking down at the storm, showing low-level inflow entering from the south (the bottom of the drawing), the main updraft within the storm shown by the dotted circle, upper-level environmental airflow from the west and storm outflow to the east. The area within the cloud containing precipitation-sized hydrometeors is hatched. (b) Cross section south to north parallel to the inflow, with the upper-level flow away from the reader. The trajectory indicated by open circles in both views represents direct growth in the main updraft: condensation, freezing, and some riming leading to small ice particles that travel more or less with the air and out into the upper-level anvil. The trajectory indicated by the solid circles indicates particles that start in weaker upward flow on the south side of the updraft, grow to larger sizes and higher fall velocities and fall as small hail or rain to the north of the location of the main updraft. The trajectory indicated by the numbers – 1, 2, 3 – represent large hail formation: (1) slow growth rising at the west side of the updraft, (2) descent back into the inflow while traveling in the environmental flow around the south side of the updraft, and (3) final growth as hail within the strong updraft and fallout at its northern edge. Adapted from Browning, K.A., 1977. In: Foote, G.B., Knight, C.A. (Eds.), *Hail: A Review of Hail Science and Hail Suppression*. American Meteorological Society, Boston, pp. 1–47, by permission of AMS.

become hail embryos, getting a chance to grow further while rising a second time within the updraft. Falling faster with respect to the air, they ascend more slowly and have time to grow into full-fledged hailstones.

This is a particularly simple and organized recycling of precipitation particles to form hail embryos in a storm: simplified because even most supercells are not especially in steady state, but evolve in various ways.

Multicell storms, on the other hand, are composed of individual convective cells that grow and decay in proximity to one another, sometimes in a systematic way. The individual cells may last 45–60 min, as their updrafts increase up to a maximum and then die out. This can be enough time to produce significant hail, and if the initial updraft is not too strong, embryos may have time to grow and attain a fall speed of several meters per second without being elevated too high in the cloud. Now as the updraft strengthens the embryos may already be there in the right locations and ready to form hailstones.

Multicell hailstorms typically produce spotty, discontinuous hailfalls, which may be organized within a larger hailstorm if the multicell is an organized one or may be distributed irregularly.

Hail Suppression

Hail suppression by seeding clouds with artificial ice nuclei has been practiced in many parts of the world for several decades. It is still widespread, although it is controversial and there has been no definitive demonstration of positive effects. The main idea is that, furnishing ice nuclei might increase the number of potential hail embryos in the clouds, thereby depleting the supercooled water earlier and reducing the hailstone size. If the size is reduced enough, most or all of the hail may then melt before reaching the ground. Ideally, the hail would be suppressed and the rainfall increased. There has been a great deal of discussion about optimizing the seeding materials and the timing and location of seeding, but the knowledge of the natural evolution of the ice contents within hailstorms is still rudimentary, so it may be many years before a consensus is reached on the prospects of hail suppression.

Hail Climatology

Hailfall at the ground is a small-scale phenomenon generally affecting areas of one to a few tens of square kilometers, though much larger hailfalls have been documented. It is highly variable and poorly resolved by routine weather observation networks. In many countries, most reports come from target-of-opportunity observations from members of the general public or public safety officials. In some limited areas, hailpad networks provide measurements of hail size, but in most parts of the world, size is estimated. Many small hailfalls are missed altogether. Thus, data on hail climatology are statistical in nature and much of the information derives from insurance records. Recently, estimates based on the environmental conditions in which hail occurs have been

developed, but they are based on data from North America (see Figure 9 in **Weather Forecasting: Severe Weather Forecasting**).

Consideration of the environments favorable for hail formation leads to understanding the preferred locations of hailfall. Exceptionally high humidity at low levels along with exceptionally cold temperatures aloft are the ingredients for the instability that leads to thunderstorm updrafts strong enough to support large hail. Strong changes of the horizontal wind with height (as depicted in **Figure 5(a)**) also contribute to updraft velocity by influencing the vertical pressure gradient. Both of these influences are common to the east of high mountain ranges in middle latitudes. The predominant westerlies aloft, over warm, moist winds from nearer the equator near the ground, are the reason why thunderstorms with large hail are generally found east of the Rocky Mountains in North America, the Andes in South America, and the Himalayas in Asia. Although the regions east of those three large mountain ranges are where the largest hail (>5 cm diameter) most commonly falls, areas near the Pyrenees and Alps experience smaller hail where both the instability and the wind shear are usually less pronounced. With the high-value and sensitive crops in those regions, such as wine grapes, crop losses from small hail can be very important.

Tropical thunderstorms are less likely to produce hail than their midlatitude counterparts for two primary reasons. First, there is less atmospheric instability, so that updrafts may not be as strong, and second, the height of the freezing level is far above the ground. As a result, hail that forms tends to be small and melt on the way down, arriving at the surface as rain. Hail is rare at high latitudes because conditions are generally too cold and dry for thunderstorms.

Some global climate simulations predict an increase in the frequency of severe, hail-producing thunderstorms in the future. However, observations from China have indicated that the frequency of hail occurrence has decreased since the mid-1980s. Using radiosonde observations and a simple one-dimensional model of hail growth, this decrease has been associated with an observed rise in the freezing level as a result of increasing surface temperatures, indicating that the melting of hail on the way to the ground may have dominated any potential for increased creation of hail. Hailpad studies from France and Italy have indicated a slight tendency for a shift in hail size distributions toward larger sizes since the mid-1980s, consistent with the production of larger hail aloft, but with preferential melting of the small, slower-falling hail below the freezing level.

Hail Detection by Radar

Radar methods for remote sensing of hail within clouds have recently come into use for research but not yet for the operational radar networks. These rely on varying the polarization of the transmitted pulses and sensing different polarizations of the backscattered radiation. Horizontal and vertical linear polarizations are often used, and sometimes circular polarization. Intense radar echoes may be caused either by heavy rain or by hail, and until recently the interpretation has been ambiguous. However, big raindrops are consistently flattened, with larger horizontal than vertical dimensions, and this produces a substantially stronger echo with a horizontally than a vertically polarized radar. Hail gives a more nearly equal radar echo strength at the two polarizations because small hail is not flattened and larger hail tumbles so that its elongations are about equally distributed in space. Thus the difference, termed the differential reflectivity, is used as a hail signal when the radar echo itself is intense.

Widespread application of this and other advanced radar techniques will greatly increase the knowledge of hail production as related to storm structure and behavior, especially if techniques are developed to provide information about hail size and amount within storms. Radar sensing of hail, if developed to be sufficiently quantitative and used routinely, would also contribute greatly to hail climatology and hail research.

Synopsis

Mesoscale convective systems are organized, multicellular thunderstorm systems that have a strong impact on heavy rainfall, severe weather, and vertical transport in the atmosphere. The significant types in terms of those impacts range from bow echoes at smaller scales, which cause damaging surface winds, to mesoscale convective complexes with mesoscale convective vortices at larger scales, which can produce persistent, widespread heavy rainfall and flash flooding. This article describes their structure, life cycle, large-scale environments, global distribution, impact on heat and moisture transport, chemical transport, and electricity.

Introduction

A mesoscale convective system (MCS) is an organized, multicellular thunderstorm system marked by an extensive mid- to upper-level stratiform cloud shield. Tropical and warm-season convections in midlatitudes are most often organized into mesoscale systems with length scales of 100–1000 km and typical lifetimes of 6–12 h. The definition encompasses a continuous spectrum of phenomena including midlatitude squall lines, bow echoes, mesoscale convective complexes (MCCs), tropical squall and nonsquall clusters, small multicellular storms, and even some tropical cyclones. They typically begin as cumulonimbus along a low-level convergence boundary then merge and organize upscale to form a single cloud system with large contiguous areas of rain (on the order of 100 km). A midtropospheric mesoscale convective vortex (MCV) sometimes forms in the stratiform region, can focus new convection, and may contribute to tropical cyclone genesis. Their mode of organization, strength, and longevity depend on variables such as the vertical shear, the strength of the low-level convergence, the convective available potential energy (CAPE, Appendix), and the distribution of moisture.

These systems have garnered much attention mainly because of their strong impact on heavy rainfall, severe weather, and vertical transport. The significant MCSs in terms of those impacts range from bow echoes at smaller scales, which cause damaging surface winds, to MCCs with MCVs at larger scales, which can produce persistent, widespread heavy rainfall and flash flooding. This article describes, in turn, their structure, life cycle, large-scale environment, global distribution, impact on heating and moisture transport, chemical transport, and electricity.

Structure and Life Cycle

The structure and life cycle of MCSs strongly depends on the environmental wind shear. How the system organizes and evolves depends on the balance between the horizontal vorticity of the cold pool generated by convection and horizontal vorticity associated with the low- to midtropospheric shear. The Coriolis force also influences the structure of long-lasting MCSs, particularly in the midlatitudes. MCSs become

more asymmetric with stronger Coriolis force and develop larger areas of rain on their poleward side.

Midlatitude Squall Lines (Linear MCS)

The term 'squall line' applies to any line of rapidly moving thunderstorms including large multicellular storms organized along a line, i.e., a linear MCS with length scales of 1000 km along the line and 100 km normal to the line. Squall lines are the most common type of midlatitude MCS and severe lines are most frequent in the spring, producing twice as many tornadoes, high wind, and hail as more circular MCSs.

Spring squall lines have four primary modes of genesis that all evolve into a quasi-linear MCS. A radar study of 55 major rain events over six springs in Oklahoma showed that most MCSs have a contiguous region of deep convective cells and an associated region of stratiform rain. The precipitation pattern comprises a continuous spectrum of mesoscale structures. Initial organization is into convective lines followed by stratiform rain regions with slantwise front-to-rear ascent and rear-to-front descent (Figure 1). Two-thirds of those systems were classified as asymmetric, a categorization more applicable to an MCS stage than type. Typical surface features are presquall mesolow (due to subsidence warming in the mid-to-upper troposphere), mesohigh (due to heavy precipitation and convective-scale downdrafts), and wake low (due to subsidence warming and as a surface manifestation of the descending rear-inflow jet (RIJ)). Another study of 88 linear MCSs over the US Great Plains found that 60% had similar leading line/trailing stratiform structure while those with stratiform rain *ahead* of or *parallel* to the convective line each accounted for about 20% (Figure 2).

Mesoscale Convective Complex

The MCC is a large, quasi-circular, meso- α -scale (length scale 250–2500 km) convective system that meets size, shape, and duration criteria based on satellite infrared brightness temperature (Table 1). Their association with devastating flash floods has been recognized since the late 1970s. Note that, with the exception of size, no significant differences in characteristics exist between MCCs and slightly smaller quasi-circular MCSs. The MCC definition succeeds in identifying the largest,

long-lived convective systems that are important for hydro-meteorological purposes.

All populations of MCCs (Table 2) exhibit a nocturnal life cycle. First thunderstorms usually develop in the mid- to late afternoon; a single organized system initiates by early nighttime; reaches its maximum extent after midnight; and dissipates shortly after daybreak (Figure 3).

MCCs have mean cloud shield areas of 350 000 km² and persist for an average of 11 h. Oceanic systems are, on average, slightly larger and longer lasting but less intense in terms of cloud top temperature and radar reflectivity. Not surprisingly, size and duration are positively correlated, with summer correlation values nearly twice the spring and fall. It appears that a meso- β -scale convective cycle that occurs early in the growth phase distinguishes the long-lived MCCs from other shorter-lived MCSs. Strong growth within the first 3 h is a strong predictor of the maximum extent and duration of MCCs.

In contrast to the uniform cloud top signature, MCC precipitation is highly varied. In the 1985 Oklahoma-Kansas Preliminary Regional Experiment for Stormscale Operational

Research Meteorology Central-Phase (PRE-STORM), 75% of MCCs matched the MCC criteria and displayed asymmetric precipitation patterns. Although the internal structure of some MCCs resembles linear MCSs, the surface weather can be quite different. Squall line passage is noted for more precipitous temperature, dew point, and wind changes than MCCs, which have longer periods of steady rain and rain showers.

Peak precipitation rates (over 25 mm h⁻¹) occur in the 2–6 h period after initiation and favor the equatorward flank, contributing to the reflectivity and precipitation pattern depicted in Figure 1. The growth stage also produces hail, high winds, and tornadoes. As the cloud system matures, the overall rain rate decreases, becomes more stratiform, and the rain area expands. The stratiform rainfall, 30–40% of the system total, is associated with mesoscale ascent inside clouds extending upward from the melting level. After 10–12 h, rainfall ends and deep convection ceases. A 10-year study of extreme warm season rainfall found that 22% of extreme rainfall in the Central United States occurred in MCCs, although less than 9% of all precipitation observations occurred in MCCs. Thus, MCCs

produce extreme rainfall at a far greater rate than that produced by other sources.

MCCs and smaller circular MCSs, beneficially, contribute 30–70% of the growing season precipitation in the US Central Plains. Other locations with large MCC populations, like southeastern China, Sahelian Africa, and subtropical South America, rely on deep convection for a significant portion of their summer season rainfall. For example, during 1998–2007 the MCC contribution to rainfall in subtropical South America was 11–20% for all months and 30–50% for the midsummer. In southeastern Africa, MCCs contribute 20–24% of summertime rainfall. However, there is considerable interannual and spatial variability, with MCCs accounting for up to 40% in some warm seasons.

Bow Echo

A line of strong convective cells or a single large convective cell can evolve into an MCS known as a bow echo, because of its characteristic bow shape on radar displays. The typical evolution of a bow echo is shown in Figure 4, a pattern observed in single cells or squall lines of hundreds of kilometers horizontal scale. Bow echoes cause wide and long swaths of severe, straight-line winds called *derechos*. Derechos are defined as a family of downburst clusters with winds exceeding 33 m s^{-1} (64 kts) across an area whose major axis is at least 400 km. Large MCSs can produce multiple bow echoes and derechos.

Prominent features of bow echoes include a strong RIJ, which, if it descends to the surface, is likely to produce

Figure 3 Life cycle of the global population of MCCs (----- first thunderstorm; --- initialization; — maximum extent; and --- termination).

damaging winds, and a rear-inflow notch, which is often evident just before and during the initial formation of the bow. Vortices, known as bookend vortices, form on the ends of the convective line. In longer-lived bow echoes, the Coriolis force

promotes stronger cyclonic shear behind the poleward end of the bow and weak anticyclonic shear equatorward of the bow (Figure 4).

Tropical Squall and Nonsquall Clusters

Tropical squall cluster or squall line is identified by a line of vigorous convective cells extending for hundreds to thousands of kilometers along its major axis. The typical tropical squall line, in prevailing easterly flow, has a rearward tilting updraft, and expanding stratiform rain area as the system matures (Figure 5).

Typical squall clusters move rapidly westward as a continuous disturbance or family of systems that can propagate for several days while undergoing cycles of regeneration. Some West African squall clusters could be classified as MCCs from their satellite signature while Amazon squall lines tend to elongate over time. Table 2 summarizes the climatology of various squall line populations.

Squall line passage is noted for a distinct roll cloud followed by a sudden wind squall. A heavy downpour then sets in, often producing 30 mm of rainfall in about 30 min. Vigorous convection is then replaced by stratiform rainfall (about 40% of system total) continuing for several hours.

Figure 5 Schematic diagram of the kinematic structure and radar echoes of a tropical squall line with trailing stratiform rain from initial convection to maturity; viewed as a cross section perpendicular to the convective line and its motion. © The COMET Program. https://www.meted.ucar.edu/about_legal.php.

Beneath the melting level, evaporative cooling of precipitation drives mesoscale downdrafts in the wake of the squall (Figure 5). Some convection in the tropical Pacific and tropical North Africa have a 2-day cycle, with daytime surface heat initiating a strong MCS that matures at night, then

downdrafts from the MCS stabilizing the boundary layer the next day.

Eastward-moving tropical squall lines, under westerly steering winds, occur in the monsoon regions of Asia, Australia, the western tropical Pacific, and, occasionally, in

tropical South America. For large MCSs or superclusters, observed by Doppler radar over the western tropical Pacific, updrafts consist of layers of potentially unstable air that nearly always ascend slantwise over an apparent downdraft cold pool. Inflow layers of 0.5–4.5 km in depth form convective cells as soon as the rising layer becomes saturated but retain their layered structure, phenomena now known as moist absolutely unstable layers.

Tropical nonsquall clusters occur more frequently than squall clusters and possess more varied precipitation structures although their precipitation life cycle is similar to that of squall lines and MCCs.

MCS Propagation

It has been suggested that MCSs propagate via mechanisms such as (1) new convection forming along the cold pool boundary; (2) discrete propagation, in which the MCS propagation vector is the cold pool vector (approximated by the mean cloud layer wind) plus a low-level jet (LLJ) vector; (3) waves generated by the MCS itself, such as gravity waves, force new cells in the near MCS environment; (4) advection by large-scale waves to which the MCS becomes phase-locked; and (5) formation of a midlevel mesoscale vortex and new convection with a different velocity than the initial MCS.

Large-Scale Environments

The Role of Topography

Global climatologies have shown that most MCSs form in the lee of elevated terrain, which act as heat sources in response to diurnal heating. Large-scale, mountain–plains solenoidal circulations help to organize MCSs during summertime in the midlatitudes and certain regions of tropical continents. In a typical diurnal cycle, convection initiates over elevated or sloping terrain then propagates coherently downstream in moderate vertical shear while growing and merging into mesoscale systems.

Midlatitude Squall Lines

Squall lines are observed frequently in the warm sector of a midlatitude cyclone, usually about 100–300 km in advance of the cold front. Divergence ahead of an upper-level trough induces low-level convergence. The advection of warm, moist air by an LLJ, sometimes accompanied by cold advection in the upper-level jet stream, provides a source of instability and promotes long-lived systems (Figure 6).

Over the US southern Plains, low–midtropospheric warm, dry air from the Mexican plateau meets the warm, humid air from the Gulf of Mexico along a moisture boundary known as the ‘dry line.’ Dry-air intrusion produces a capping inversion that leads to great instability (CAPE) and more intense squall lines. This scenario is common elsewhere, such as east of the subtropical Andes, the South African escarpment, and southeast Australia. Squall lines are also triggered along coastlines, due to differential surface heating, and wind shear lines.

Increasing mid- to upper-level shear marks midlatitude squall line environments. Large quantities of dry air are entrained into the rear of the system, cooled, moistened, and sink, thereby strengthening the downdraft. The resulting cold pool and gust front enhances the system updraft and leads to greater intensity and longevity. The cold pool acts as a gravity current because it is denser than its environment and new convection forms by uplift along its boundary. The organization of the mature system is strongly governed by the vertical wind shear and the strength of the cold pool. Other predictors of intensity and longevity are the strength of the midlevel winds, the low-level storm-relative flow, and shear from the surface to midtroposphere. Midlatitude squall lines can be maintained with moderate midlevel shear, which is generally destructive to tropical squall lines.

Mesoscale Convective Complexes

MCCs initiate within prominent baroclinic zones (like stationary fronts) characterized by locally large values of lower-tropospheric vertical wind shear and CAPE. Typically, an LLJ of air with low static stability, high equivalent potential

Figure 6 Schematic diagram of the large-scale features associated with midlatitude prefrontal squall lines.

temperature (θ_e), oriented nearly perpendicular to the baroclinic zone, intrudes into the genesis region, and is forced to ascend over a relatively shallow, surface-based layer of relatively cool air (Figure 7). Pronounced warm advection accompanied by strong lower-tropospheric veering overlays the surface-based cool layer. Local maxima in absolute humidity and static instability mark the preferred MCC formation region. Low-level convergence, upper-level divergence, and an approaching midlevel vorticity maximum related to a weak shortwave trough are also characteristics of the mean genesis

environment. In most instances, an upper-level jet is present in the near vicinity.

The thermodynamic structure and flow of the mean MCC environments suggest that low-level slantwise ascent along sloping potential temperature surfaces in regions of lower-tropospheric warm advection is an inherent part of most MCC environments. The low-level warm advection coupled with differential cyclonic vorticity advection forces upward motion throughout the troposphere, with maximum values near midtroposphere.

Figure 7 Analyses of the mean synoptic environment of 12 US MCCs: temperature, geopotential height, q_e , and wind vectors for (a) 1000 hPa and (b) 850 hPa; geopotential height, mixing ratio, and wind vectors for (c) 700 hPa; geopotential height, vorticity, and wind vectors for (d) 500 hPa; (e) K-index (KI) (Appendix); and geopotential height, divergence, and wind vectors for (f) 200 hPa. The quadrilateral in the center indicates the approximate genesis region (GR). Velocity vectors (m s^{-1}) are plotted at every other grid point. Heights (m) and KI values are solid contours, isotherms ($^{\circ}\text{C}$) are dashed, and hachured areas are (a) $q_e > 350 \text{ K}$, (b) $q_e > 338 \text{ K}$, and (c) mixing ratio $> 5 \text{ g kg}^{-1}$. The letters U and S identify the relatively unstable and stable areas, respectively, in (e). Bold velocity vectors, in (a) and (b), highlight the low-level inflow of high- q_e air and 850-hPa warm advection, respectively. Bold vectors also mark wind speed maxima in (d) and (f). The 500-hPa absolute vorticity ($\times 10^{-5} \text{ s}^{-1}$) is shown by dashed lines in (d). Shaded areas in (f) are divergence $> 4 \times 10^{-6} \text{ s}^{-1}$. Reproduced from Laing, A.G., Fritsch, J.M., 2000. The large-scale environments of the global population of mesoscale convective complexes. *Monthly Weather Review* 128, 2756–2776.

Although most MCCs form in conjunction with frontal lifting, a significant number (about 40% in the United States) develop on the warm side of the baroclinic zone (Figure 8). A favorable combination of a convectively generated cold pool and substantial low-level vertical wind shear can produce long-lived convective weather systems with a deep layer of slantwise ascent and a large stratiform cloud region *without large-scale forcing*. Figure 9 shows the conceptual models of MCC configurations. Figure 9(a) is similar to the squall line arrangement, except that, because of an LLJ, the ambient shear in the cold pool is opposite to the squall line case. Therefore, the cold-pool-induced circulation always has the same sign as the ambient shear. This device is also likely in tropical MCC populations that have weak baroclinic forcing. Nevertheless, it is unlikely that this mechanism would dictate the organization of most MCCs, for which convection originates from an elevated layer of high- θ_e air overrunning a quasi-stationary surface-based frontal zone (Figure 9(b)). It is difficult for moist downdrafts to penetrate to the surface and form a mesoscale cold pool. However, if a cold pool were to develop, because of the LLJ the ambient shear would have the same sign as any convectively derived cold pool. That configuration would also produce slantwise ascent and a large stratiform cloud layer.

Mature MCCs contain three distinct circulations: a large, cold, and shallow anticyclone in the vicinity of the tropopause, a boundary layer cold mesohigh, and, in the midlevels, strong latent heating, convergence, and a mesoscale updraft. MCCs moisten a deep tropospheric layer, and amplify the midlevel

Figure 8 Examples of two types of North American MCCs: one in Canada on the cool side of the stationary front (dominant type) and another in the US Southern Plains on the warm side of the front at 1200 UTC, 6 May 2000. Arrows show the direction of movement of the MCCs.

shortwave trough as it adjusts to latent heating. The LLJ strengthens, veers, and helps to maintain high moisture and maximum conditional instability in the southwestern flank of the system (a region susceptible to floods). An anticyclonically curved upper-level jet streak develops to the north of the MCC. Near maximum mean upward motion, upper-tropospheric divergence, and vorticity occur throughout the mature stage and is maintained through the decay stage.

Once outside the region of conditionally unstable air and low-level warm advection, the system decays leaving a significantly modified environment extending beyond the MCC boundary, including an amplified midlevel shortwave trough and high upper-tropospheric heights and wind perturbations.

LLJ and Movement of MCCs

The presence of LLJs in MCC environments around the globe implies that the jet helps to organize and maintain mesoscale convection. Detailed investigations of MCCs in the United States, South America, and China showed that pronounced convergence occurs at the apex of the jet and that vertical motion from the jet dramatically increases the moist convective instability (e.g., Figure 6). Furthermore, *the temporal evolution (evening into early morning) and the orientation of the LLJ closely parallel the nocturnal life cycle and movement, respectively, of MCSs*.

MCC motion vector is approximated by summing the mean from 700- to 500-hPa flow parallel to thickness isopleths, a proxy for propagation of the meso- β -scale elements (MBEs), and the LLJ vector. Studies of US MCCs found that, as the system mature the MBEs move about 45° to the right of the mean flow, partly due to the MCC modifying the mean environmental wind. Extreme right movers account for about 25% of US MCCs and they produce derechos. MCCs become quasi-stationary or build backward if the moist, unstable inflow is toward the rear, then new cells form upstream (to the west in the midlatitudes).

Bow Echoes

Bow echoes and derechos most commonly occur in an environment with strong, deep layer shear in combination with high CAPE, steep midlevel lapse rates, and a strong cold pool. Derecho-producing environments can be distinguished from nonderecho environments by the strength of shear and the system-relative flow in the lowest 3 km. About half of derechos in the United States during 1980–2001 had shear magnitudes greater than 20 m s^{-1} . *Progressive* derechos are prevalent when the bow is oriented with a large angle to the mean wind direction and moves for hundreds of kilometer along a quasi-stationary front while *serial* derechos occur when multiple bow echoes are embedded in a long squall line and move along the direction of the mean steering wind.

Tropical Squall Line/Clusters

The dominant large-scale forcing of squall lines in the western Pacific and tropical Atlantic is convergence in the equatorial trough, monsoon trough, and intertropical convergence zone. Systems observed during the Global Atmospheric Research Program Atlantic Tropical Experiment (GATE) formed several

Figure 9 Storm evolution in contrasting environments: thin circling arrows indicate circulations affiliated with ambient wind shear and/or a moist-downdraft-generated cold pool. (a) Cold pool forms in the warm sector. The circulation induced by the cold pool combines with the circulation associated with the shear to tilt the system downstream and downshear (northward). (If the shear-induced circulation is of the opposite sign, the cold-pool circulation overwhelms the shear and tilts upshear, northward, over the cold pool.) (b) LLJ overruns a frontal zone. Negative buoyancy of moist downdrafts is insufficient to penetrate to the base of the synoptic-scale cold air layer, so a surface-based mesoscale cold pool does not develop. The letters W and E indicate southwesterly and easterly winds, respectively. The edge of the cloud system is scalloped. Reproduced from Laing, A.G., Fritsch, J.M., 2000. The large-scale environments of the global population of mesoscale convective complexes. *Monthly Weather Review* 128, 2756–2776.

hours after large-scale convergence was established and moisture flux increased in the low-middle troposphere. Postsquall environments are characterized by lower-tropospheric warming and drying.

While most tropical MCS generation is correlated with topography, vertical shear, high CAPE, and diurnal heating, some squall lines occur with African easterly waves. Squall lines associated with easterly waves most often form ahead of or within the easterly wave trough, move at about twice the speed of the wave, and tend to die just behind the ridge. However, in the northern Sahel, MCSs form within and behind the trough, in the region of maximum convergence of moisture from southerly monsoon winds. Amazon squall lines have added forcing from the sea breeze front.

Tropical squall line development is aided by strong low-level wind shear. For GATE squall lines, the critical threshold was 13 m s^{-1} in the 950- to 650-hPa layer, mostly perpendicular to the leading line. Squall lines, in turn, transport momentum *up-gradient*, increasing the vertical wind shear.

Tropical MCS environments include topographic effects and gravity waves. For example, mesoscale convection over northwest South America is initiated by elevated heating over the

Andes, which induces sea breeze inflow. Convection then moves westward over the tropical Pacific because of a gravity wave response to the elevated heating. During the day, a warm anomaly over the ocean caps convection while after sunset, cooling over the elevated terrain causes a nearby gravity wave response of upward motion in the lower troposphere. Thus, allowing convection to develop over the ocean at night. Similar mechanisms operate over the northern South China Sea except with extra forcing from an onshore LLJ. Another theory is suggested for nocturnal, offshore mesoscale convection downstream of tropical mountains. The mountain blocks the sea breeze current, thereby producing relatively cold, stagnant air at the base of the mountain, which then produces a stronger land-breeze density current and triggers convection far offshore.

Tropical Nonsquall Clusters

The environment of nonsquall clusters is similar to squall clusters in terms of conditional instability and formation relative to the easterly wave trough. However, large, longer-lived nonsquall clusters tend to move at less than the speed of the easterly wave and dissipate once they fall behind the

trough axis. GATE clusters are formed where mean 950- to 650-hPa environmental shear was about 6 m s^{-1} and mostly parallel to the lines. A distinctive feature of nonsquall cluster environments is the absence of strong shear between 700 and 250 hPa. Winter monsoon clusters west of Borneo are initiated by the low-level convergence of offshore breezes, northeasterly monsoon wind surges, and synoptic-scale Borneo vortices, which form when northeasterly monsoon winds curve to the east and north near the equator. MCS formation over the South China Sea and Borneo is suppressed on days without a vortex and enhanced further downstream.

Composite nonsquall cluster environments have maximum low-level convergence during the growing stage of the system life cycle. The maximum vertical motion is close to 300 hPa and occurs during the mature phase in contrast to midlatitude MCCs whose maximum vertical motion occurs during the mature-to-dissipating phase.

Basically, environments with weak shear in the middle levels and deep layer moisture tend to produce more

MCCs and nonsquall clusters while strongly sheared environments with dry-air inflow at middle levels favor more linear MCS.

Impact of Tropical Waves and the Madden-Julian Oscillation

Tropical mesoscale convection is sometimes coupled to equatorially trapped waves such as Rossby-gravity waves and Kelvin waves. The Madden-Julian Oscillation (MJO), the dominant mode of intraseasonal variability in the tropics, also modulates MCS activity. The propagation of tropical MCSs is affected by variations in the large-scale wind velocity in the lower troposphere and near the tropopause, as occurs with convectively coupled equatorial waves and the MJO. For example, during the wet phase of convectively coupled Kelvin waves, MCSs are larger and have higher cold cloud tops. Daily initiation and westward propagation of MCSs continue within the wave envelope while the dry phase has few, weak systems (Figure 10).

Figure 10 (a) Enhanced IR images for 5–8 April 2002. (b) Theoretical equatorially trapped Kelvin wave circulation at 200 hPa. (c) Hovmöller of brightness temperature $<233 \text{ K}$ frequency (solid contours 10%, gray shade 21%) overlaid on 200-hPa zonal wind anomaly (orange shades are easterly, turquoise shades are westerly) and Kelvin waves filtered from daily outgoing long-wave radiation (OLR) anomaly (negative is dashed black, positive is solid black at 20 W m^{-2} intervals). Average elevation (m) is below the Hovmöller diagram in (c). Averages are taken between 7.5° S and 7.5° N . Part (c) is reproduced from Laing, A.G., Carbone, R.E., Levizzani, V., 2011. Global Distribution

Mesoscale Convective Complex

MCCs occur frequently (300–400 annually, Table 3) but in certain preferred locations (Figure 11). Most MCCs: (1) occur overland; (2)

develop in belts of easterlies and westerlies; and (3) tend to form in the lee of high terrain (association with LLJs). It is intriguing to note that MCCs are rare in some locations where deep moist convection including squall lines is common, e.g., the Amazon River basin or the Southeastern United States (Figure 10).

Table 3 MCC populations included in the global data set

MCC data sets			
Region/period of study	Geographic domain	Avg no. per season (high–low annual range)	Reference
South, Central America, May 1981–Apr 1983	40° S–30° N, 120–28° W	96 (47)	Velasco and Fritsch (1987)
Western Pacific Region, 1983, 1985	50° S–50° N, 90° E–170° W	82 (14)	Miller (1990)
United States, 1986–87	25–50° N, 130–70° W	51 (14)	Augustine and Howard (1991)
Africa, 1986–87	40° S–35° N, 45° W–45° E	97 (7)	Laing (1992)
Indian subcontinent, Apr–Dec 1988	0–50° N, 45–110° E	49	Laing (1992)
Europe, 1986–87	35–55° N, 20° W–45° E	6 (1)	Laing and Fritsch (1997)
Total		381 (83)

Table 4 SSM/I-derived ice scattering definition for MCS and intense MCS based on polarization corrected temperature (PCT)

MCS	Minimum area	2000 km ²
	Contour PCT	250 K
	Minimum enclosed PCT	≤225 K
Intense MCS	Minimum area	2000 km ²
	Contour PCT	200 K
	Minimum enclosed PCT	≤175 K

Adapted from Mohr, K.I., Zipser, E.J., 1996. Mesoscale convective systems defined by their 85-GHz ice scattering signature: size and intensity comparison over tropical oceans and continents. *Monthly Weather Review* 124, 2417–2437.

Midlatitude MCC activity is most frequent from June to August in the Northern Hemisphere and November to February in the Southern Hemisphere. The latitudinal progression of all MCS activities is related to the seasonal migration of large-scale circulation patterns and the migration varies substantially from region to region. During summer in northern continents, when the poleward shift in the jet stream is pronounced, MCC activity shifts strongly poleward. In the ocean-dominated hemisphere, where jet streams are quasi-stationary, poleward migration is not as evident.

Tropical MCS

Tropical MCS climatologies were developed using Special Sensor Microwave Imager (SSM/I) and the Tropical Rainfall Measurement Mission (TRMM) satellite measurements. Systems were classified according to their 85-GHz ice scattering signature to distinguish mesoscale regions of convectively produced large ice particles aloft (Table 4), the maximum heights of the 30-dBZ contour, and 6-km reflectivities (Table 5). MCSs are most prevalent over tropical South America, tropical Africa, and the oceanic warm pool (similar locations to Figure 11). They are 60% more frequent over continents at sunset than at sunrise and 35% more frequent over the oceans at sunrise than at sunset. Except over subtropical oceans, MCSs are larger at sunrise than at sunset. The total population forms a continuous, approximately log normal, distribution with the frequency inversely proportional to the area and intensity. No significant

relationship was found between size and intensity. Intense MCSs, which accounted for only 4% of the SSM/I-derived database, were mainly continental, colder than oceanic systems, and more occurred in the subtropics than in the tropics, a pattern confirmed by TRMM measurements. The reverse is true for rain area as oceanic intense MCSs contained a larger area of rain than continental intense MCS. The most intense systems, those with reflectivity of 20 dBZ reaching 14 km or higher, are most frequent over the African Congo, a significant fraction are also found in subtropical South American, northern India/Bangladesh, areas also favored for MCC development.

Heating and Moist Convective Transport

The propensity of convective cells to organize into mesoscale systems has important implications for the large-scale circulation and heat budget because convection has a greater impact on the large-scale when organized into mesoscale systems than as individual thunderstorms.

In examining the transport of heat and moisture, it helps to consider an ensemble of cumulus clouds embedded in a large-scale circulation. The heat and moisture budget can be expressed as:

$$Q_1 - Q_R = Q_{1c} + Q_{1m}$$

$$Q_2 = Q_{2c} + Q_{2m}$$

where Q_R is the net radiative heating, Q_1 and Q_2 are the residuals from the budgets of the 'resolvable' motion called the apparent heat source and moisture sink, respectively. When the budgets are divided into cumulus (Q_{1c} , Q_{2c}) and mesoscale (Q_{1m} , Q_{2m}) stratiform components, the stratiform exerts great influence on the overall vertical heating profile with cooling below the melting level and warming above (Figure 12(a) and 12(b)). Midlatitude MCSs generally have a sharper peak in heating and at a higher level than tropical MCSs (Figure 12(c)). Heating characteristics vary even among tropical MCSs. Maximum heating in Western Pacific MCSs occurs in the mid-to upper levels during the mature-to-decaying stages while GATE systems experience maximum heating earlier and in the lower troposphere.

Table 5 Criteria used to classify three precipitation feature (PF) types, based on the TRMM Microwave Imager (TMI) and Precipitation Radar (PR) data

Category name	Data	Criteria
PF with an MCS	PR near-surface reflectivity and nearest neighbor TMI 85-GHz PCT (within the PR swath)	● 108 or more contiguous data bins (area ≥2000 km²) with PCT ≤250 K with associated PR rain area ● 10 or more data bins (area 185 km²) with PCT ≤225 K
PF with ice scattering and without an MCS	PR near-surface reflectivity and nearest neighbor TMI 85-GHz PCT (within the PR swath)	● 4 or more contiguous data bins (area ≥75 km²) with a PR near-surface reflectivity ≥20 dBZ or a PCT ≤250 K ● At least one data bin with PCT ≤250 K ● Does not meet the PF with an MCS criteria
PF without ice scattering (250 K)	PR near-surface reflectivity and nearest neighbor TMI 85-GHz PCT (within the PR swath)	● 4 or more contiguous data bins (area ≤75 km²) with a PR near-surface reflectivity ≥20 dBZ ● No data bins contain PCTs ≤250 K
